Diabetes associated with pancreatic endocrine failure may be difficult to control, with a rapid progression from oral hypoglycaemic agents to an insulin requirement. Brittle control is a common problem secondary to inadequate glucagon production from the damaged pancreas.

Complications

The most common structural complication of chronic pancreatitis is a *pancreatic pseudocyst*, a fluid collection surrounded by granulation tissue (see p. 364). These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intra- or retroperitoneal rupture, bleeding or cyst infection may occur. The larger cysts may occlude nearby

structures including the duodenum and the bile duct. In pseudocysts less than 6 cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period in excess of 6 weeks, resolution is less common and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely apposed to the posterior wall of the stomach or duodenum and can be successfully drained endoscopically using endoscopic ultrasound to identify the optimum drainage site. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen which is then kept patent by the insertion of plastic stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances in which the pseudocyst anatomy does not allow endoscopic access.

Ascites and occasionally pleural effusions can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high ascites or pleural fluid amylase will confirm the aetiology. Such disruptions of the main pancreatic duct require surgical intervention.

There is an increased risk of pancreatic cancer in patients with chronic pancreatitis. This may be as high as 15% in patients with alcohol-associated disease. The highest incidence has been reported in hereditary pancreatitis when the lifetime risk is as high as 40%. This has prompted the introduction of surveillance programmes for this very high risk group, usually starting around the age of 40 years and relying upon yearly imaging and tumour marker measurement.

Cystic fibrosis

Some 85% of people with cystic fibrosis (see p. 44 and Chapter 16) will have pancreatic failure, and in the majority of these, this will develop *in utero* and be present from the perinatal period.

Treatment of pancreatic disease

The management of pancreatic insufficiency is necessary to optimize the growth and overall nutrition. Pancreatic supplements are closely titrated against the level of steatorrhoea. Fat intake should be maintained to avoid nutritional deficit. Enteric-coated supplements should be taken during the meal. A daily lipase intake of up to 10000 units/kg bodyweight is required. Higher doses of enteric-coated preparations are available but have been implicated in right-sided colon stricture formation in children. The exact mechanism is unknown but these preparations are no longer recommended in children.

Increasing the jejunal pH with an H_2 -receptor antagonist or a proton pump inhibitor can improve absorption. About 11% of patients will develop clinically significant diabetes mellitus, often insulin dependent.

CARCINOMA OF THE PANCREAS

Incidence of pancreatic cancer in the West has been estimated at approximately 10 cases per 100000, with no increase over the last 20 years. Pancreatic cancer is now the fifth most common cause of cancer death in the western world. The incidence increases with age and the majority of cases occur in patients over the age of 60. Approximately 60% of patients with this condition are male. Some 96% of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin.

Aetiology. Smoking is associated with a two-fold increase. Excess intake of alcohol, intake of coffee and use of aspirin

have been implicated. There is an increased incidence of pancreatic cancer among patients with a history of diabetes and chronic pancreatitis. Approximately 5–10% of patients with pancreatic cancer have a family history of the disease.

Pathogenesis. In some patients, pancreatic cancer develops as part of a well-defined cancer-predisposing syndrome for which germline genetic alterations are known (Table 7.23). A genetic factor has been suggested, as the risk of pancreatic cancer is 57 times as high in families with four or more affected members as in families with no affected members. The genetic bases for these associations are not known, although a subgroup of such high-risk kindred carry germline mutations of DNA repair genes such as *BRCA2* and the partner and localizer of *BRCA2*.

Data suggest that pancreatic cancer results from the successive accumulation of gene mutations. The cancer originates in the ductal epithelium and evolves from premalignant lesions to fully invasive cancer. The lesion called pancreatic intraepithelial neoplasia (PanIN) is the best-characterized histologic precursor of pancreatic cancer. The progression from minimally dysplastic epithelium (PanIN grades 1A and 1B) to more severe dysplasia (grades 2 and 3) and finally to invasive carcinoma is paralleled by the successive accumulation of mutations that include activation of the *KRAS2* oncogene, inactivation of the tumour-suppressor gene *CDKN2A* (which encodes the inhibitor of cyclin-dependent kinase 4 [*INK4A*]), and, last, inactivation of the tumour-suppressor genes *TP53* and deleted in pancreatic cancer 4 (*DPC4*, also known as the SMAD family member 4 gene [*SMAD4*]) (Fig. 7.42).

A small percentage of pancreatic adenocarcinomas arise from cystic lesions including intraductal papillary mucinous tumours (IPMT) and mucinous cystic neoplasia (see below).

There is evidence that these cystic neoplasms demonstrate a similar multistep genetic and histological progression to invasive adenocarcinoma.

Clinical picture

Pancreatic adenocarcinoma may be viewed clinically as two diseases – the lesions of the head and lesions of the body and tail.

Symptoms

Head of pancreas and the ampulla of Vater. This is the most frequent site for cancer to develop. It tends to present earlier with obstruction to the bile duct as this passes through the head of pancreas giving jaundice (Fig. 7.43). These more localized lesions are usually painless, although pain may become a feature with tumour progression. Obstruction of the pancreatic duct may lead to symptomatic episodes of pancreatitis. Pancreatic damage secondary to duct obstruction is frequently associated with abnormalities of glucose homeostasis. Pancreatic cancer should be considered in the differential diagnoses of acute pancreatitis and newly diagnosed diabetes.

Carcinoma localized to the body or tail of the pancreas is much more likely to present with abdominal pain as well as nonspecific symptoms such as anorexia and weight loss. The pain is often dull in character with radiation through into the back. A characteristic feature is partial relief of pain by sitting forward. Bile duct obstruction and jaundice may infrequently be late phenomena.

Physical signs

Carcinoma of the head of pancreas. The patient is jaundiced with characteristic scratch marks secondary to cholestasis. In a proportion of cases, the gall bladder will be palpable (Courvoisier's sign). With metastatic disease, a central abdominal mass may be palpable as well as hepatomegaly.

Carcinoma of the body and tail. There are often no physical signs.

Other presenting physical signs include thromboembolic phenomena, polyarthritis and skin nodules. The latter are secondary to localized fat necrosis and associated inflammation. These manifestations, distant to the tumour itself, have not been fully explained but may precede the overt presentation of pancreatic cancer by months to years.

Investigations

- **Transabdominal ultrasound** is the initial investigation in the majority of patients. In the presence of bile duct

Carcinoma of the pancreas

Figure 7.43 Carcinoma of the head of the pancreas. A diagrammatic representation of the close relationship of a carcinoma of the head of pancreas to the surrounding structures.

Figure 7.44 A contrast-enhanced CT scan showing a cancer of the body of the pancreas. There is retroperitoneal tumour extension enclosing the branches of the coeliac axis (arrow).

obstruction this will confirm dilated intrahepatic bile ducts as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, with a sensitivity of detection of 60%.

- **Contrast-enhanced CT scan** should confirm the presence of a mass lesion (Fig. 7.44). It is also necessary prior to possible surgical resection with contrast providing vascular definition to exclude tumour invasion as well as local lymph node involvement and distant metastases.
- **Laparoscopy** is also used for preoperative assessment.
- **ERCP** is usually restricted to palliative treatment but may provide a source of cytology to confirm the diagnosis when this is in question.
- **Percutaneous needle biopsy** is discouraged in potentially operable cases as this may be a source of tumour cell spread within the peritoneum. If palliative chemotherapy is considered, a histological diagnosis is essential prior to treatment.

Figure 7.45 Pancreatic cancer. An endoscopic ultrasound scan with the probe in the distal stomach. The patient presented with intractable periumbilical pain. A mass lesion of the pancreatic body is defined (tumour). There is invasion by the lesion into the splenic vein (SV) (vasc invasion). The line of a trans-endoscopic needle is seen (needle tip), which has been placed under the guidance of the ultrasound probe to obtain a needle aspirate for cytological diagnosis.

- **MRI scanning and endoscopic ultrasound** are techniques that are useful in a small proportion of patients in whom the tumour has not been adequately defined. Endoscopic ultrasound is now the technique of choice to obtain histological/cytological confirmation of malignancy (Fig. 7.45).
- **Several tumour markers** have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19-9 has a high sensitivity (80%) but a high false-positive rate. In individual patients, single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic, and in such circumstances tumour marker levels can be used to monitor response to treatment.

Differential diagnosis

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss. Unfortunately, many patients present with very minor symptoms including pain, change in bowel habit and weight loss. Imaging, particularly abdominal CT, should be performed if pancreatic cancer is suspected. IgG4-related autoimmune pancreatitis is now recognized as a differential diagnosis in patients presenting with abdominal pain, possible jaundice and an abnormal pancreas on imaging (localised or diffuse enlargement) (see above). Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

Management

The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection but in an elderly population many of these have co-morbid factors that preclude such major surgery. To optimize the percentage of patients undergoing possible surgical resection it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

Obstructive jaundice will occur at some stage in 70% of cases and is a debilitating complication, often associated with severe pruritus but also the cause of nonspecific malaise, lethargy and anorexia.

- Endoscopic placement of endoprotheses (stents) offers excellent palliation with a low associated procedural morbidity and mortality (see above).
- Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases) but in advanced disease self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.
- Radiotherapy results have been disappointing (see p. 479).
- Chemotherapeutic agents (see p. 479) have been shown to have survival benefit in patients treated as adjuvant therapy to pancreatic resection. New targeted agents are in clinical development.

With disease progression, abdominal pain is a frequent complicating factor which may prove extremely difficult to treat. This is best managed by experienced palliative care teams which offer a multidisciplinary approach. Endocrine and exocrine pancreatic failure occur and are managed as described on [page 366](#).

CYSTIC TUMOURS OF THE PANCREAS

Cystic lesions of the pancreas are not uncommon. Seventy-five per cent of these lesions will be pseudocysts (see above) but of the remainder the majority are true cystic neoplasms.

Serous cyst adenomas are composed of multiple small cystic cavities lined by cuboidal glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare. Larger serous cystadenomas may cause local compressive complications (when over approximately 5 cm).

Mucinous cyst adenomas are almost exclusively found in women in the 5th and 6th decades and are sited in the pancreatic body and tail. Multilocular cysts are lined by tall mucin-synthesizing cells. Of these lesions, 20% are malignant at the time of presentation and the majority appear to have a malignant potential. As a consequence, they are much more likely to produce symptoms.

Intraductal papillary mucinous tumour (IPMT) is a pancreatic cystic neoplasm that can arise from either the side branches or the main duct. The majority are found in men between the ages of 60 and 70. The presentation is usually with pancreatic pain but may be an incidental finding. The lesion is slowly progressive with a significant malignant potential; this appears to be more so when the main duct is the site of origin.

There is a high potential for the development of malignancy in cystic lesions and therefore resection is usually appropriate. The decision-making process may be difficult in patients with small (<3 cm) lesions of the head of pancreas (in the absence of confirmed malignancy at presentation) and in whom there are significant risks associated with surgery. An initial conservative approach with follow-up imaging may be justified. The differentiation between pseudocysts and true cystic neoplasms may be difficult, even with multiple imaging techniques. Patients with pseudocysts may have a history

of pancreatitis. Endoscopic ultrasound scanning and fine-needle aspiration can be helpful in the differentiation. The measurement of cyst fluid CEA and CA19-9 may help to identify malignant change.

NEUROENDOCRINE TUMOURS OF THE PANCREAS

The incidence and prevalence of pancreatic endocrine tumours have increased during the last two decades, reaching an incidence of 4–5/1 000 000 population. They represent a heterogeneous group of tumours with varying tumour biology and prognosis and 40–50% of the patients present with symptoms related to the substances released from the tumours (see below). The remainder are referred to as ‘non-functioning’ and usually present with symptoms related to tumour bulk such as obstruction, jaundice, bleeding and abdominal mass. Of pancreatic endocrine tumours, 10–15% are linked to an inherited syndrome such as the multiple endocrine neoplasia type 1 (MEN-1).

Diagnosis is based upon a combination of biochemical and histopathological markers. The histopathology includes features such as positive staining for chromogranin A and specific hormones such as gastrin, proinsulin, and glucagon. The biochemical diagnosis includes measurement of circulatory chromogranin A or specific hormones such as gastrin, insulin, glucagon and vasoactive intestinal polypeptide (VIP).

Investigation and management

Tumour localization depends upon cross-sectional imaging, including CT and MRI scanning. The majority of neuroendocrine tumours express somatostatin receptors and can be mapped by scintigraphy. Recently, positron emission tomography (PET scanning) with specific isotopes such as ¹¹C-5-hydroxytryptamine (¹¹C-5-HTP), fluorodopa and ⁶⁸Ga (DOTA)-octreotate have been introduced.

Where possible, surgery of the primary lesion is the optimal management of pancreatic endocrine tumours. The propensity of many endocrine tumours to metastasize early precludes cure in many cases. Debulking of the tumour including liver metastases is frequently carried out to facilitate systemic treatment. The chemotherapeutic agents, streptozotocin, 5-fluorouracil and doxorubicin, produce partial remission in approximately 40% of cases.

Somatostatin analogues are used to control hormonal related symptoms and also have a tumour modulating effect. Recent advances include the introduction of tyrosine kinase and the mammalian target of rapamycin (mTOR) inhibitors (see p. 446). Radionuclide therapy using somatostatin analogues has proven benefit in patients with tumours that express high content of somatostatin receptors. In the future, treatment will be based on individualized tumour biology and molecular genetics.

The islets of Langerhans ([p. 360](#)) have the capacity to synthesize more than one hormone. They also synthesize ectopic hormones that are not usually found in the pancreas such as gastrin, adrenocorticotrophin, vasoactive intestinal peptide and growth hormone. While many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for the clinical syndrome. Other tumours, while containing peptide hormone, are functionally inactive.

These tumours are rare with an incidence of less than 1 in 100 000 of the population. Insulinomas are the commonest

variant (50%), gastrinomas account for 20% and the rarer functioning tumours 5%. The remaining 25% are non-functioning tumours. Approximately 25% of islet cell tumours are associated with a multiple endocrine neoplasia syndrome (type 1) (see p. 997). The majority of the endocrine neoplasia pancreatic tumours are malignant in their behaviour.

Presentation of pancreatic neuroendocrine tumours is most commonly related to the actions of ectopic hormone secretion. Identification of the primary and possibly metastatic lesions may be difficult despite multiple imaging techniques. Endoscopic ultrasound may be the most sensitive means of detecting small tumours. Many of these tumours have somatostatin receptors, and radiolabelled somatostatin analogue (such as octreotide) scanning provides a means of tumour localization.

Treatment options for pancreatic neuroendocrine tumours require a multidisciplinary approach and depend upon the presence or absence of metastatic (usually hepatic) disease. *Surgical resection* of the pancreatic lesion is the only potential curative approach. Aggressive surgical intervention including a resection of the primary lesion as well as liver resection for metastasis has been used in selected cases. Somatostatin analogues such as octreotide and lanreotide have been used specifically for the control of symptoms secondary to the hormonal secretion.

There is some evidence that the somatostatin analogues combined with interferon- α also control tumour proliferation. The chemotherapeutic agents, streptozotocin, 5-fluorouracil and doxorubicin, produce partial remission in approximately 40% of cases. Pancreatic neuroendocrine tumours show a very high degree of vascularization as well as abundant production and secretion of growth factors. There is preliminary evidence of benefit from antiangiogenesis therapy utilizing vascular endothelial growth factor (VEGF) antagonists. Antagonists to a number of oncogenic growth factors are currently under investigation.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for many years.

Clinical syndromes

Insulinoma is described on page 1031.

A **gastrinoma** accounts for approximately 1 in 1000 cases of duodenal ulcer disease. This results from hypersecretion of gastric acid secondary to ectopic gastrin secretion within the endocrine pancreas (Zollinger–Ellison syndrome). Recurrent severe duodenal ulceration occurs with only a partial response to acid suppression. The diagnosis is confirmed by an elevated gastrin level. High-dose proton pump inhibitors are used to suppress symptoms.

A **VIPoma** is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes a severe secretory diarrhoea secondary to the stimulation of adenyl cyclase within the enterocyte (Verner–Morrison syndrome). The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter.

Glucagonomas are rare α -cell tumours which are responsible for the syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia and hypoalbuminaemia. The diagnosis is made by measuring pancreatic glucagon in the serum.

Somatostatinomas are rare malignant D cell tumours of the pancreas and 30% occur in the duodenum and small bowel. These tumours cause diabetes mellitus, gallstones and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels.

INTRODUCTION AND GENERAL ASPECTS

Blood consists of:

- Red cells
- White cells
- Platelets
- Plasma, in which the above elements are suspended.

Plasma is the liquid component of blood, which contains soluble fibrinogen. Serum is what remains after the formation of the fibrin clot.

The formation of blood cells (haemopoiesis)

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes and thymus. There is huge turnover of cells with the red cells surviving 120 days, platelets around 7 days but granulocytes only 7 hours. The production of as many as 10^{13} new myeloid cells (all blood cells except for lymphocytes) per day in the normal healthy state requires tight regulation according to the needs of the body.

Blood islands are formed in the yolk sac in the 3rd week of gestation and produce primitive blood cells, which migrate

to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks to 7 months, when the bone marrow becomes the main source of blood cells. However, in childhood and adult life, the bone marrow is the only source of blood cells in a normal person.

At birth, haemopoiesis is present in the marrow of nearly every bone. As the child grows, the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends of the long bones. Only if the demand for blood cells increases and persists do the areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as *extramedullary haemopoiesis*.

All blood cells are derived from pluripotent stem cells. These stem cells are supported by stromal cells (see below), which also influence haemopoiesis. The stem cell has two properties – the first is *self-renewal*, i.e. the production of more stem cells, and the second is its *proliferation and differentiation* into progenitor cells, committed to one specific cell line.

There are two major ancestral cell lines derived from the pluripotential stem cell: lymphocytic and myeloid (non-lymphocytic) cells (Fig. 8.1). The former gives rise to T and B cells. The myeloid stem cell gives rise to the progenitor

Figure 8.1 Role of growth factors in normal haemopoiesis. Some of the multiple growth factors acting on stem cells and early progenitor cells are shown. baso, basophil; BFU, burst-forming unit; CFU, colony-forming unit; CSF, colony-stimulating factor; E, erythroid; Eo, eosinophil; EPO, erythropoietin; G, granulocyte; GEMM, mixed granulocyte, erythroid, monocyte, megakaryocyte; GM, granulocyte, monocyte; IL, interleukin; M, monocyte; Meg, megakaryocyte; SCF, stem cell (Steel) factor or C-kit ligand; TNF, tumour necrosis factor; TPO, thrombopoietin.

CFU-GEMM (colony-forming unit, granulocyte-erythrocyte-monocyte-megakaryocyte). The CFU-GEMM can go on to form CFU-GM, CFU-Eo, and CFU-Meg, each of which can produce a particular cell type (i.e. neutrophils, eosinophils and platelets) under appropriate growth conditions. The progenitor cells such as CFU-GEMM cannot be recognized in bone marrow biopsies but are recognized by their ability to form colonies when haemopoietic cells are immobilized in a soft gel matrix. Haemopoiesis is under the control of growth factors and inhibitors, and the microenvironment of the bone marrow also plays a role in its regulation.

Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins, which regulate the differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. They act on the cytokine-receptor superfamily expressed on haemopoietic cells at various stages of development to maintain the

haemopoietic progenitor cells and to stimulate increased production of one or more cell lines in response to stresses such as blood loss and infection (Fig. 8.1).

These haemopoietic growth factors including erythropoietin, interleukin 3 (IL-3), IL-6, -7, -11, -12, β -catenin, stem cell factor (SCF, Steel factor or C-kit ligand) and Fms-tyrosine kinase 3 (Flt3) act via their specific receptor on cell surfaces to stimulate the cytoplasmic janus kinase (JAK) (see p. 25). This major signal transducer activates tyrosine kinase causing gene activation in the cell nucleus. Colony-stimulating factors (CSFs, the prefix indicating the cell type, see Fig. 8.1), as well as interleukins and erythropoietin (EPO) regulate the lineage committed progenitor cells.

Thrombopoietin (TPO, which, like erythropoietin, is produced in the kidneys and the liver) controls platelet production, along with IL-6 and IL-11. In addition to these factors stimulating haemopoiesis, other factors inhibit the process and include tumour necrosis factor (TNF) and transforming growth factor- β (TGF- β). Many of the growth factors are

produced by activated T cells, monocytes and bone marrow stromal cells such as fibroblasts, endothelial cells and macrophages; these cells are also involved in inflammatory responses. Bone marrow stem cells can differentiate into other organ cell types, e.g. heart, liver, nerves, bone and this is called *stem cell plasticity*.

Uses in treatment

Many growth factors have been produced by recombinant DNA techniques and are being used clinically. Examples include granulocyte-colony-stimulating factor (G-CSF), which is used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation, and erythropoietin, which is used to treat anaemia in patients with chronic kidney disease. Thrombopoietin receptor agonists are being used to treat patients with immune thrombocytopenic purpura.

Stem cell diseases

The clonal proliferation of bone marrow stem cells leads to diseases including leukaemia (see p. 451), polycythaemia vera (see p. 402), myelofibrosis (see p. 404), paroxysmal nocturnal haemoglobinuria (see p. 401). Failure of stem cell growth leads to aplastic anaemia (see p. 385).

Peripheral blood

Automated cell counters are used to measure the haemoglobin concentration (Hb) and the number and size of red cells, white cells and platelets (Table 8.1). Other indices can be derived from these values. A carefully evaluated blood film is still an essential adjunct to the above, as definitive abnormalities of cells can be seen.

- **The mean corpuscular volume (MCV)** of red cells is a useful index and is used to classify anaemia (see p. 376).
- **The red cell distribution width (RDW)** is calculated by dividing the *standard deviation* of the red cell width by the *mean cell width* $\times 100$. An elevated RDW suggests variation in red cell size, i.e. anisocytosis, and this is seen in iron deficiency. In β -thalassaemia trait, the RDW is usually normal.
- **The white cell count (WCC)**, (or WBC, white blood count) gives the total number of circulating leucocytes,

and many automated cell counters produce differential counts as well.

- **Reticulocytes** are young red cells and usually comprise <2% of the red cells. The reticulocyte count gives a guide to the erythroid activity in the bone marrow. An increased count is seen with increased marrow maturity, e.g. following haemorrhage or haemolysis, and during the response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure (from whatever cause) or where there is a deficiency of a haematinic.
- **Erythrocyte sedimentation rate (ESR)** is the rate of fall of red cells in a column of blood and is a measure of the acute-phase response. The pathological process may be immunological, infective, ischaemic, malignant or traumatic. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, with red cells clumping together and therefore falling more rapidly. The ESR increases with age, and is higher in females than in males.
- **Plasma viscosity** is a measurement used instead of the ESR in some laboratories. It is also dependent on the concentration of large molecules such as fibrinogen and immunoglobulins. It is not affected by the level of Hb.
- **C-reactive protein (CRP)** is a pentraxin, one of the proteins produced in the acute-phase response. It is synthesized exclusively in the liver and rises within 6 hours of an acute event. The CRP level rises with fever (possibly triggered by IL-1, IL-6 and TNF- α and other cytokines), in inflammatory conditions and after trauma. It follows the clinical state of the patient much more rapidly than the ESR and is unaffected by the level of Hb, but it is less helpful than the ESR or plasma viscosity in monitoring chronic inflammatory diseases. The measurement of CRP is easy and quick to perform using an immunoassay that can be automated. High-sensitivity assays have shown that increased levels may predict future cardiovascular disease (see p. 728).

Introduction and general aspects

The red cell

THE RED CELL

Erythropoiesis

Red cell precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are pronormoblasts. Smaller normoblasts result from cell divisions, and precursors at each stage progressively contain less RNA and more Hb in the cytoplasm. The nucleus becomes more condensed and is eventually lost from the late normoblast in the bone marrow when the cell becomes a reticulocyte.

- **Reticulocytes** contain residual ribosomal RNA and are still able to synthesize Hb. They remain in the marrow for about 1–2 days and are released into the circulation, where they lose their RNA and become mature red cells (erythrocytes) after another 1–2 days. Mature red cells are non-nucleated biconcave discs.
- Nucleated red cells (**normoblasts**) are not normally present in peripheral blood, but are present if there is extramedullary haemopoiesis and in some marrow disorders (see leucoerythroblastic anaemia, p. 413).

Table 8.1 Normal values for peripheral blood

	Male	Female
Hb (g/L)	135–175	115–160
PCV (haematocrit; L/L)	0.4–0.54	0.37–0.47
RCC ($10^{12}/L$)	4.5–6.0	3.9–5.0
MCV (fL)	80–96	
MCH (pg)	27–32

- About 10% of **erythroblasts** die in the bone marrow even during normal erythropoiesis. Such ineffective erythropoiesis is substantially increased in some anaemias such as thalassaemia major and megaloblastic anaemia.
- **Erythropoietin** is a hormone which controls erythropoiesis. The gene for erythropoietin is on chromosome 7 and codes for a heavily glycosylated polypeptide of 165 amino acids. Erythropoietin has a molecular weight of 30 400 and is produced in the peritubular cells in the kidneys (90%) and in the liver (10%). Its production is regulated mainly by tissue oxygen tension. Production is increased if there is hypoxia from whatever cause, e.g. anaemia or cardiac or pulmonary disease. The erythropoietin gene is one of a number of genes that is regulated by the hypoxic sensor pathway. The 3'-flanking region of the erythropoietin gene has a hypoxic response element, which is necessary for the induction of transcription of the gene in hypoxic cells. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor, which binds to the hypoxia response element and acts as a master regulator of several genes that are responsive to hypoxia. Erythropoietin stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis, and CFU-E are stimulated to proliferate and differentiate. Increased 'inappropriate' production of erythropoietin occurs in certain tumours such as renal cell carcinoma and other causes (see Table 8.15).

Haemoglobin synthesis

Haemoglobin performs the main functions of red cells – carrying O_2 to the tissues and returning CO_2 from the tissues to the lungs. Each normal adult Hb molecule (HbA) has a molecular weight of 68 000 and consists of two α and two β globin polypeptide chains ($\alpha_2\beta_2$). HbA comprises about 97% of the Hb in adults. Two other haemoglobin types, HbA₂ ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), are found in adults in small amounts (1.5–3.2% and <1%, respectively) (see p. 390).

Haemoglobin synthesis occurs in the mitochondria of the developing red cell (Fig. 8.2). The major rate-limiting step is the conversion of glycine and succinic acid to δ -aminolaevulinic acid (ALA) by ALA synthase. Vitamin B₆ is a coenzyme for this reaction, which is inhibited by haem and stimulated by erythropoietin. Two molecules of δ -ALA condense to form a pyrrole ring (prophobilinogen). These rings are then grouped in fours to produce protoporphyrins and with the addition of iron haem is formed. Haem is then inserted into the globin chains to form a haemoglobin molecule. The structure of Hb is shown in Figure 8.3.

Haemoglobin function

The biconcave shape of red cells provides a large surface area for the uptake and release of oxygen and carbon dioxide. Haemoglobin becomes saturated with oxygen in the pulmonary capillaries where the partial pressure of oxygen is high and Hb has a high affinity for oxygen. Oxygen is released in the tissues where the partial pressure of oxygen is low and Hb has a low affinity for oxygen.

In adult haemoglobin (Hb), a haem group is bound to each of the four globin chains; the haem group has a porphyrin ring with a ferrous atom which can reversibly bind one oxygen molecule. The haemoglobin molecule exists in two

Figure 8.2 Haemoglobin synthesis. Transferrin attaches to a surface receptor on developing red cells. Iron is released and transported to the mitochondria, where it combines with protoporphyrin to form haem. Protoporphyrin itself is manufactured from glycine and succinyl-CoA. Haem combines with α and β chains (formed on ribosomes) to make haemoglobin.

Figure 8.3 Model of the haemoglobin molecule showing α (red) and β (blue) chains. 2,3-BPG (bisphosphoglycerate) binds in the centre of the molecule and stabilizes the deoxygenated form by cross-linking the β chains (also see Fig. 8.4). M, methyl; P, propionic acid; V, vinyl.

Figure 8.4 Oxygenated and deoxygenated haemoglobin molecule. The haemoglobin molecule is predominantly stabilized by α - β chain bonds rather than α - α and β - β chain bonds. The structure of the molecule changes during O_2 uptake and release. When O_2 is released, the β chains rotate on the $\alpha_1\beta_2$ and $\alpha_2\beta_1$ contacts, allowing the entry of 2,3-BPG which causes a lower affinity of haemoglobin for O_2 and improved delivery of O_2 to the tissues.

conformations, R and T. The T (taut) conformation of deoxyhaemoglobin is characterized by the globin units being held tightly together by electrostatic bonds (Fig. 8.4). These bonds are broken when oxygen binds to haemoglobin, resulting in the R (relaxed) conformation in which the remaining oxygen binding sites are more exposed and have a much higher affinity for oxygen than in the T conformation. The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites – this property is known as ‘cooperativity’ and is the reason for the sigmoid shape of the oxygen dissociation curve. Haemoglobin is, therefore, an example of an allosteric protein. The binding of oxygen can be influenced by secondary effectors – hydrogen ions, carbon dioxide and red-cell 2,3-bisphosphoglycerate (2,3-BPG). Hydrogen ions and carbon dioxide added to blood cause a reduction in the oxygen-binding affinity of haemoglobin (the Bohr effect). Oxygenation of haemoglobin reduces its affinity for carbon dioxide (the Haldane effect). These effects help the exchange of carbon dioxide and oxygen in the tissues.

Red cell metabolism produces 2,3-BPG from glycolysis. 2,3-BPG accumulates because it is sequestered by binding to deoxyhaemoglobin. The binding of 2,3-BPG stabilizes the T conformation and reduces its affinity for oxygen. The P_{50} is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. P_{50} increases with 2,3-BPG concentrations, which increase when oxygen availability is reduced in conditions such as hypoxia or anaemia. P_{50} also rises with increasing body temperature, which may be beneficial during prolonged exercise. Haemoglobin regulates oxygen transport as shown in the oxyhaemoglobin dissociation curve. When the primary limitation to oxygen transport is in the periphery, e.g. heavy exercise, anaemia, the P_{50} is increased to enhance oxygen unloading. When the primary limitation is in the lungs, e.g. lung disease, high altitude exposure, the P_{50} is reduced to enhance oxygen loading.

A summary of normal red cell production and destruction is given in Figure 8.5.

Figure 8.5 Red cell production and breakdown (see p. 307).

individual (Table 8.1). Alterations in the Hb may occur as a result of changes in the plasma volume, as shown in Figure 8.6. A reduction in the plasma volume will lead to a spuriously high Hb – this is seen with dehydration and in the clinical condition of apparent polycythaemia (see p. 404). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume as occurs in pregnancy.

The various types of anaemia, classified by MCV, are shown in Figure 8.7. There are three major types:

- Hypochromic microcytic with a low MCV
- Normochromic normocytic with a normal MCV
- Macrocytic with a high MCV.

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of Hb allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to

ANAEMIA

Anaemia is present when there is a decrease in Hb in the blood below the reference level for the age and sex of the

FURTHER READING

Kaushansky K. Lineage-specific hematopoietic growth factors. *N Engl J Med* 2006; 354:2034–2045.

the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms (all nonspecific)

- Fatigue, headaches and faintness
- Breathlessness
- Angina
- Intermittent claudication
- Palpitations.

Anaemia exacerbates cardiorespiratory problems especially in the elderly. For example, angina or intermittent claudication may be precipitated by anaemia. A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exercise (e.g. walking on the flat or climbing one flight of stairs).

Signs

- Pallor
- Tachycardia
- Systolic flow murmur
- Cardiac failure.

Figure 8.6 Alterations of haemoglobin in relation to plasma.

Specific signs seen in the different types of anaemia will be discussed in the appropriate sections. Examples include:

- Koilonychia – spoon-shaped nails seen in longstanding iron deficiency anaemia
- Jaundice – found in haemolytic anaemia
- Bone deformities – found in thalassaemia major
- Leg ulcers – occur in association with sickle cell disease.

It must be emphasized that anaemia is not a final diagnosis, and a cause should be sought.

Investigations

Peripheral blood

A low Hb should always be evaluated with:

- The red cell indices
- The white blood cell (WBC) count
- The platelet count
- The reticulocyte count (as this indicates marrow activity)
- The blood film, as abnormal red cell morphology (see Fig. 8.9) may indicate the diagnosis. Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with 'double deficiencies' (e.g. combined iron and folate deficiency in coeliac disease, or following treatment of anaemic patients with the appropriate haematinic).

Bone marrow

Techniques for obtaining bone marrow are shown in [Practical Box 8.1](#).

Examination of the bone marrow is performed to further investigate abnormalities found in the peripheral blood ([Practical Box 8.1](#)). Aspiration provides a film which can be examined by microscopy for the morphology of the developing haemopoietic cells. The trephine provides a core of bone which is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates.

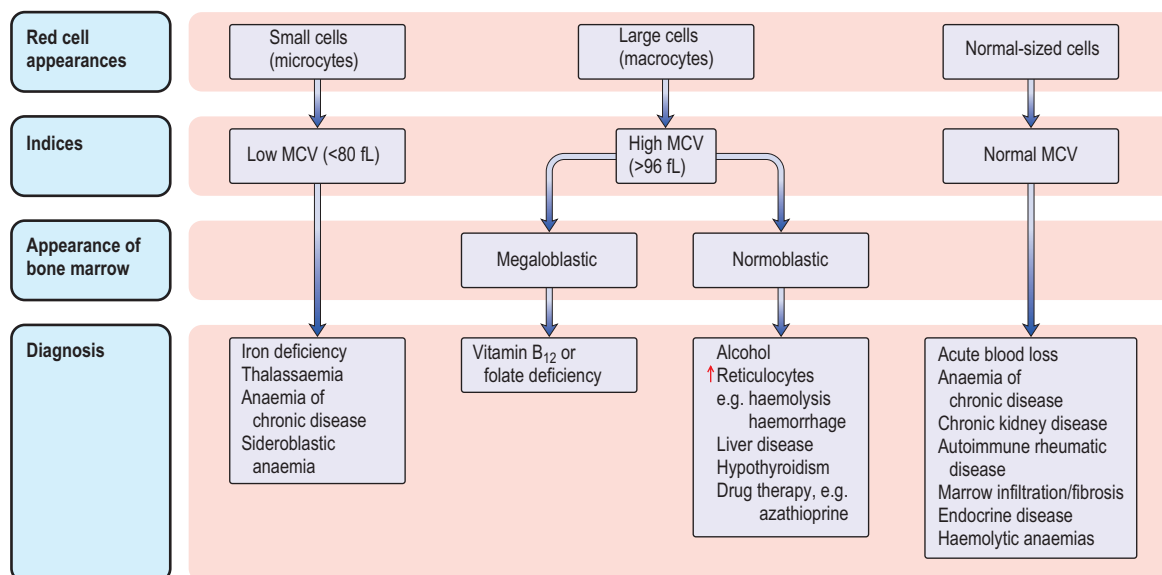

Figure 8.7 Classification of anaemia. MCV, mean corpuscular volume.

**Practical Box 8.1****Techniques for obtaining bone marrow**

The technique should be explained to the patient and consent obtained.

Aspiration

- Site – usually iliac crest
- Give local anaesthetic injection
- Use special bone marrow needle (e.g. Salah)
- Aspirate marrow
- Make smear with glass slide
- Stain with:
 - Romanowsky technique
 - Perl's reaction (acid ferrocyanide) for iron

Trephine

Indications include:

- 'Dry tap' obtained with aspiration
- Better assessment of cellularity, e.g. aplastic anaemia
- Better assessment of presence of infiltration or fibrosis

Technique

- Site – usually posterior iliac crest
- Give local anaesthetic injection
- Use special needle (e.g. Jamshidi – longer and wider than for aspiration)
- Obtain core of bone
- Fix in formalin; decalcify – this takes a few days
- Stain with:
 - Haematoxylin and eosin
 - Reticulin stain

The following are assessed:

- Cellularity of the marrow
- Type of erythropoiesis (e.g. normoblastic or megaloblastic)
- Cellularity of the various cell lines
- Infiltration of the marrow, i.e. presence of non-haematopoietic cells such as cancer cells
- Iron stores.

Special tests may be performed for further diagnosis: cytogenetic, immunological, cytochemical markers, biochemical analyses and microbiological culture.

MICROCYTIC ANAEMIA

Iron deficiency is the most common cause of anaemia in the world, affecting 30% of the world's population. This is because of the body's limited ability to absorb iron and the frequent loss of iron owing to haemorrhage. Although iron is abundant, most is in the insoluble ferric (Fe^{3+}) form, which has poor bioavailability. Ferrous (Fe^{2+}) is more readily absorbed.

The other causes of a microcytic hypochromic anaemia are anaemia of chronic disease, sideroblastic anaemia and thalassaemia. In thalassaemia (see p. 390), there is a defect in globin synthesis, in contrast to the other three causes of microcytic anaemia where the defect is in the synthesis of haem.

Iron**Dietary intake**

The average daily diet in the UK contains 15–20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20–30% in iron deficiency and pregnancy.

Table 8.2 Factors influencing iron absorption

<p>Haem iron is absorbed better than non-haem iron</p> <p>Ferrous iron is absorbed better than ferric iron</p> <p>Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut</p> <p>Formation of insoluble complexes with phytate or phosphate decreases iron absorption</p> <p>Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g. bleeding, haemolysis, high altitude</p> <p>There is a decreased absorption in iron overload, except in hereditary haemochromatosis, where it is increased</p>

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

Absorption

Factors influencing iron and haem iron absorption (Fig. 8.8) are shown in Table 8.2.

Dietary haem iron is more rapidly absorbed than non-haem iron derived from vegetables and grain. Most haem is absorbed in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter HCP1 (haem carrier protein 1) has been identified and found to be highly expressed in the duodenum. It is upregulated by hypoxia and iron deficiency. Some haem iron may be reabsorbed intact into circulation via the cell by two exporter proteins – BCRP (breast cancer resistant protein) and FLVCR (feline leukaemia virus subgroup C) (Fig. 8.8).

Non-haem iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body's iron requirements and retain this information as they mature into cells capable of absorbing iron at the tips of the villi. A protein, divalent metal transporter 1 (DMT1) or natural resistance-associated macrophage protein (NRAMP2), transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body's iron status at the time the absorptive cell developed from the crypt cell is probably the crucial deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (FPN 1) through its iron-responsive element (IRE). This transporter protein requires an accessory, multicopper protein, hephaestin (Fig. 8.8).

The body iron content is closely regulated by the control of iron absorption but there is no physiological mechanism for eliminating excess iron from the body. The key molecule regulating iron absorption is *hepcidin*, a 25 amino acid peptide synthesized in the liver. Hepcidin acts by regulating the activity of the iron exporting protein ferroportin by binding to ferroportin causing its internalization and degradation, thereby decreasing iron efflux from iron exporting tissues into plasma. Therefore, high levels of hepcidin (occurring in inflammation states) via inflammatory cytokines, e.g. IL-6 will destroy ferroportin and limit iron absorption, and low levels

Figure 8.8 (a) Regulation of the absorption of intestinal iron. The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate toward the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms, although the protein hepcidin is key. First, iron absorption is influenced by recent dietary iron intake (*dietary regulator*). After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores (*stores regulator*). Third, a signal communicates the state of bone marrow erythropoiesis to the intestine (*erythroid regulator*).

(b) Duodenal crypt cells sense body iron status through the binding of transferrin to the HFE/B₂M/TfR1 gene complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe^{3+}) to ferrous (Fe^{2+}). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells.

(c) Apical cell. Dietary iron is reduced from the ferric to the ferrous state by the brush border ferrereductase. DMT1 facilitates iron absorption from the intestinal lumen. The export proteins, e.g. ferroportin 1 and hephaestin, transfer iron from the enterocyte into the circulation depending on the hepcidin level. A second pathway absorbs intact haem iron into the circulation via BCRP and FLVCR. BCRP, breast cancer resistant protein; B2M, β_2 -microglobulin; FLVCR, feline leukaemia virus subgroup C; HCP1, haem carrier protein-1; HFE, hereditary haemochromatosis gene; TfR1, transferrin receptor.

of hepcidin (e.g. in anaemia, low iron stores, hypoxia) will encourage iron absorption. For example, in patients with haemochromatosis, mutations in the genes HFE, HJV and TfR2 will interrupt hepcidin synthesis. Therefore, in the intestinal cells, a deficiency of hepcidin would lead to less ferroportin being bound and thus more iron will be released into the plasma.

A longstanding mystery is why anaemias characterized by ineffective erythropoiesis such as thalassaemia are associated with excessive and inappropriate iron absorption. Preliminary evidence again suggests that the increased iron absorption in β -thalassaemia is mediated by downregulation of hepcidin and upregulation of ferroportin.

Transport in the blood

The normal serum iron level is about 13–32 $\mu\text{mol/L}$; there is a diurnal rhythm with higher levels in the morning. Iron is transported in the plasma bound to transferrin, a β -globulin

that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (Fig. 8.2).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5–3 g in a normal adult man). Iron is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500–1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for Hb formation. It is present in small amounts in plasma.

Haemosiderin is an insoluble iron–protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls' reaction.

Requirements

Each day 0.5–1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30–40 mL of blood/month, an average of about 0.5–0.7 mg of iron/day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg/day) and pregnancy (1–2 mg/day). In the normal adult the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- Hereditary haemochromatosis (see p. 339), where a mutation in the HFE gene causes increased iron absorption
- Secondary haemochromatosis (transfusion siderosis; see p. 391). This is due to iron overload in conditions treated by regular blood transfusion.

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. The causes are:

- Blood loss
- Increased demands such as growth and pregnancy
- Decreased absorption (e.g. post-gastrectomy)
- Poor intake.

Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. A common cause of iron deficiency worldwide is blood loss from the gastrointestinal tract resulting from parasites such as hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in developing countries. Even in developed countries, iron deficiency is not uncommon in infancy where iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

Clinical features

The symptoms of anaemia are described on page 375. The well known clinical features of iron deficiency listed below are generally only seen in cases of very longstanding iron deficiency:

- Brittle nails
- Spoon-shaped nails (koilonychia)
- Atrophy of the papillae of the tongue
- Angular stomatitis
- Brittle hair
- A syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome; see p. 243).

The diagnosis of iron deficiency anaemia relies on a clinical history which should include questions about dietary intake,

Figure 8.9 Hypochromic microcytic cells (arrow) on a blood film. Poikilocytosis (variation in size) and anisocytosis (variation in shape) are seen.

self-medication with non-steroidal anti-inflammatory drugs (which may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, a careful enquiry about the duration of periods, the occurrence of clots and the number of sanitary towels or tampons (normal 3–5/day) used should be made.

Investigations

- **Blood count and film.** A characteristic blood film is shown in Figure 8.9. The red cells are microcytic (MCV <80 fL) and hypochromic (MCH (mean corpuscular haemoglobin) <27 pg). There is poikilocytosis (variation in shape) and anisocytosis (variation in size). Target cells are seen.
- **Serum iron and iron-binding capacity.** The serum iron falls and the total iron-binding capacity (TIBC) rises in iron deficiency compared with normal. Iron deficiency is regularly present when the transferrin saturation (i.e. serum iron divided by TIBC) falls below 19% (Table 8.3).
- **Serum ferritin.** The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30–300 µg/L (11.6–144 nmol/L) in males and 15–200 µg/L (5.8–96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases. Very high levels of ferritin may be observed in hepatitis and in a rare disease, haemophagocytic lymphohistiocytosis (p. 80).
- **Serum soluble transferrin receptors.** The number of transferrin receptors increases in iron deficiency. The results of this immunoassay compare well with results from bone marrow aspiration at estimating iron stores. This assay can help to distinguish between iron deficiency and anaemia of chronic disease (Table 8.3), and may avoid the need for bone marrow examination even in complex cases. It may sometimes be helpful in the investigation of complicated causes of anaemia.
- **Other investigations.** These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 257).

Differential diagnosis

The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in Table 8.3.

Table 8.3 Microcytic anaemia: the differential diagnosis

	Iron deficiency	Anaemia of chronic disease	Thalassaemia trait (α or β)	Sideroblastic anaemia
MCV	Reduced	Low normal or normal	Very low for degree of anaemia	Low in inherited type but often raised in acquired type
Serum iron	Reduced	Reduced	Normal	Raised
Serum TIBC	Raised	Reduced	Normal	Normal
Serum ferritin	Reduced	Normal or raised	Normal	Raised
Serum soluble transfer receptors	Increased	Normal	Normal or raised	Normal or raised
Iron in marrow	Absent	Present	Present	Present
Iron in erythroblasts	Absent	Absent or reduced	Present	Ring forms
TIBC, total iron binding capacity.				

Treatment

The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. Patients with iron deficiency taking iron will increase their Hb level by approximately 10 g/L/week unless of course other factors such as bleeding are present.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate (200 mg three times daily, a total of 180 mg ferrous iron), which is absorbed best when the patient is fasting. If the patient has side-effects such as nausea, diarrhoea or constipation, taking the tablets with food or reducing the dose using a preparation with less iron such as ferrous gluconate (300 mg twice daily, only 70 mg ferrous iron) is all that is usually required to reduce the symptoms.

In developing countries, distribution of iron tablets and fortification of food are the main approaches for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, probably mainly because of poor compliance.

Oral iron should be given for long enough to correct the Hb level and to replenish the iron stores; this can take 6 months. The commonest causes of failure to respond to oral iron are:

- Lack of compliance
- Continuing haemorrhage
- Incorrect diagnosis, e.g. thalassaemia trait.

These possibilities should be considered before parenteral iron is used. However, parenteral iron is required by occasional patients, e.g. intolerant to oral preparation, severe malabsorption, chronic disease (e.g. inflammatory bowel disease). Iron stores are replaced much faster with parenteral iron than with oral iron, but the haematological response is no quicker. Parenteral iron can be given by slow intravenous infusion of low-molecular-weight iron dextran (test dose required), iron sucrose, ferric carboxymaltose, iron isomaltoside 1000; oral iron should be discontinued.

Anaemia of chronic disease

One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in patients with chronic infections such as tuberculosis or chronic inflammatory disease such as Crohn's disease, rheumatoid arthritis, systemic lupus erythematosus (SLE), polymyalgia rheumatica and malignant disease. There is decreased release of iron from the bone marrow to developing

erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival.

The exact mechanisms responsible for these effects are not clear but it seems likely that high levels of hepcidin expression play a key role (see iron absorption).

The serum iron and the TIBC are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (Table 8.3). Stainable iron is present in the bone marrow, but iron is not seen in the developing erythroblasts. Patients do not respond to iron therapy, and treatment is, in general, that of the underlying disorder. Recombinant erythropoietin therapy is used in the anaemia of renal disease (see p. 623), and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

Sideroblastic anaemia

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia, a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis forming a ring of iron granules around the nucleus that can be seen with Perls' reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias can be inherited as an X-linked disease transmitted by females. Acquired causes include myelodysplasia, myeloproliferative disorders, myeloid leukaemia, drugs (e.g. isoniazid), alcohol misuse and lead toxicity. It can also occur in other disorders such as rheumatoid arthritis, carcinomas, megaloblastic and haemolytic anaemias. A structural defect in δ -aminolaevulinic acid (ALA) synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (Fig. 8.2), has been identified in one form of inherited sideroblastic anaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see p. 405) and this is the cause of the vast majority of cases of sideroblastic anaemia in adults. Lead toxicity is described in Chapter 17.

Treatment

Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

Figure 8.10 Megaloblasts (arrowed) in the bone marrow.

Figure 8.11 Macrocytes and a hypersegmented neutrophil (arrowed) on a peripheral blood film.

Normocytic anaemia

Macrocytic anaemias

NORMOCYTIC ANAEMIA

Normocytic, normochromic anaemia is seen in anaemia of chronic disease, in some endocrine disorders (e.g. hypopituitarism, hypothyroidism and hypoadrenalism) and in some haematological disorders (e.g. aplastic anaemia and some haemolytic anaemias) (Fig. 8.7). In addition, this type of anaemia is seen acutely following blood loss.

MACROCYTIC ANAEMIAS

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

Megaloblastic anaemia

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open stippled appearance (Fig. 8.10). In addition, giant metamyelocytes are frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- Vitamin B₁₂ deficiency or abnormal vitamin B₁₂ metabolism
- Folic acid deficiency or abnormal folate metabolism
- Other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathioprine, zidovudine – AZT)
- Myelodysplasia due to dyserythropoiesis.

Haematological findings

- Anaemia may be present. The MCV is characteristically >96 fL unless there is a co-existing cause of microcytosis when there may be a dimorphic picture with a normal/low average MCV.
- The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (Fig. 8.11).
- If severe, there may be leucopenia and thrombocytopenia.

Biochemical basis of megaloblastic anaemia

The key biochemical problem common to both vitamin B₁₂ and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to

Figure 8.12 Biochemical basis of megaloblastic anaemia. The metabolic relationship between vitamin B₁₂ and folate and their role in DNA synthesis. THF, tetrahydrofolate.

deoxythymidine monophosphate, which is then used to build DNA (Fig. 8.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B₁₂ also reduces its supply by slowing the demethylation of methyltetrahydrofolate (methyl THF) and preventing cells receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are due to interference with purine or pyrimidine synthesis causing an inhibition in DNA synthesis.

Vitamin B₁₂

Vitamin B₁₂ is synthesized by certain microorganisms, and humans are ultimately dependent on animal sources. It is found in meat, fish, eggs and milk, but not in plants. Vitamin B₁₂ is not usually destroyed by cooking. The average daily

Figure 8.13 Methylcobalamin structure. This is the main form of vitamin B₁₂ in the plasma.

diet contains 5–30 µg of vitamin B₁₂, of which 2–3 µg is absorbed. The average adult stores some 2–3 mg, mainly in the liver, and it may take 2 years or more after absorptive failure before B₁₂ deficiency develops, as the daily losses are small (1–2 µg).

Structure and function

Cobalamins consist of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right-angles (Fig. 8.13). Vitamin B₁₂ was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl-, methyl- and hydroxocobalamin groups attached to the cobalt atom.

The main function of B₁₂ is the methylation of homocysteine to methionine with the demethylation of methyl THF polyglutamate to THF. THF is a substrate for folate polyglutamate synthesis.

Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Measurement of methylmalonic acid in urine was used as a test for vitamin B₁₂ deficiency but it is no longer carried out routinely.

Absorption and transport

Vitamin B₁₂ is liberated from protein complexes in food by gastric enzymes and then binds to a vitamin B₁₂-binding protein ('R' binder), which is related to *plasma transcobalamin I* (TCI) and is derived from saliva. Vitamin B₁₂ is released from the 'R' binder by pancreatic enzymes and then becomes bound to intrinsic factor.

Intrinsic factor is a glycoprotein with a molecular weight of 45 000. It is secreted by gastric parietal cells along with H⁺ ions. It combines with vitamin B₁₂ and carries it to specific receptors on the surface of the mucosa of the ileum. Vitamin B₁₂ enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B₁₂ is transported from the enterocytes to the bone marrow and other tissues by the *glycoprotein transcobalamin II* (TCII). Although TCII is the essential carrier protein for vitamin B₁₂, the amount of B₁₂ on

Table 8.4 Vitamin B₁₂ deficiency and abnormal B₁₂ utilization: further causes (see text)

Low dietary intake	Abnormal utilization
Vegans	Congenital transcobalamin II deficiency Nitrous oxide (inactivates B ₁₂)
Impaired absorption	
<i>Stomach</i>	
Pernicious anaemia Gastrectomy Congenital deficiency of intrinsic factor	
<i>Small bowel</i>	
Ileal disease or resection Bacterial overgrowth Tropical sprue Fish tapeworm (<i>Diphyllobothrium latum</i>)	

TCII is low. However, it has a rapid clearance and is able to deliver cobalamin to all cells of the body. Vitamin B₁₂ in plasma is mainly bound to TCI (70–90%), but the functional role of this protein is unknown. About 1% of an oral dose of B₁₂ is absorbed 'passively' without the need for intrinsic factor.

Vitamin B₁₂ deficiency

There are a number of causes of B₁₂ deficiency and abnormal B₁₂ metabolism (Table 8.4). The most common cause of vitamin B₁₂ deficiency in adults is pernicious anaemia. Malabsorption of vitamin B₁₂ because of pancreatitis, coeliac disease or treatment with metformin is mild and does not usually result in significant vitamin B₁₂ deficiency.

Pernicious anaemia

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa with consequent failure of intrinsic factor production and vitamin B₁₂ malabsorption.

Pathogenesis of pernicious anaemia

This disease is common in the elderly, with 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races, but occurs more frequently in fair-haired and blue-eyed individuals, and those who have the blood group A. It is more common in females than males.

There is an association with other autoimmune diseases, particularly thyroid disease, Addison's disease and vitiligo. Approximately one-half of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA – and also in many older patients with gastric atrophy. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis. Two types of intrinsic factor antibodies are found: a blocking antibody, which inhibits binding of intrinsic factor to B₁₂, and a precipitating antibody, which inhibits the binding of the B₁₂-intrinsic factor complex to its receptor site in the ileum.

B₁₂ deficiency may rarely occur in children from a congenital deficiency or abnormality of intrinsic factor, or as a result of early onset of the adult autoimmune type.

Pathology

Autoimmune gastritis (see p. 247) affecting the fundus is present with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

Clinical features

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice caused by excess breakdown of haemoglobin. A red sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum B₁₂ (<60 ng/L or 50 pmol/L) and occasionally occur in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration, see p. 1147). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions, and optic atrophy may occur from vitamin B₁₂ deficiency.

Investigations

- **Haematological findings** show the features of a megaloblastic anaemia as described on page 381.
- **Bone marrow** shows the typical features of megaloblastic erythropoiesis (Fig. 8.10), although it is frequently not performed in cases of straightforward macrocytic anaemia and a low serum vitamin B₁₂.
- **Serum bilirubin** may be raised as a result of ineffective erythropoiesis. Normally a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be increased.
- **LDH** can also be raised due to haemolysis.
- **Serum methylmalonic acid (MMA) and homocysteine (HC)** are raised in B₁₂ deficiency. They are only useful in cases where the B₁₂ and folate levels are not conclusive with only HC raised in folate deficiency.
- **Serum vitamin B₁₂** is usually well below 160 ng/L, which is the lower end of the normal range. Serum vitamin B₁₂ can be assayed using radioisotope dilution or immunological assays.
- **Serum folate level** is normal or high, and the **red cell folate** is normal or reduced owing to inhibition of normal folate synthesis.

Absorption tests

Vitamin B₁₂ absorption tests are performed only occasionally when the underlying cause of the B₁₂ deficiency is not obvious. They cannot be performed in the UK as radioactive B₁₂ is not available. However, the principle of the absorption test demonstrates how B₁₂ is absorbed.

Schilling test. Radioactive B₁₂ is given orally followed by an i.m. injection of non-radioactive B₁₂ to saturate B₁₂ binding proteins and to flush out ⁵⁸Co-B₁₂. The urine is collected for 24 h and >10% of the oral dose would be excreted in a normal person. If this is abnormal, the test is repeated with the addition of oral intrinsic factor capsules. If the excretion is now normal, the diagnosis is pernicious anaemia or gastrectomy. If the excretion is still abnormal, the lesion must be in the terminal ileum or there may be bacterial overgrowth. The latter could be confirmed by repeating the test after a course of antibiotics.

Gastrointestinal investigations

In PA there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

Differential diagnosis

Vitamin B₁₂ deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood level of these two vitamins.

Pernicious anaemia should be distinguished from other causes of vitamin B₁₂ deficiency (Table 8.4). Any disease involving the terminal ileum or bacterial overgrowth in the small bowel can produce vitamin B₁₂ deficiency (see p. 268). Gastrectomy can lead, in the long term, to vitamin B₁₂ deficiency.

Treatment

See page 384.

Folic acid

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates. Folate is present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms (Fig. 8.14), with methyl (CH₃), formyl (CHO) or methylene (CH₂) groups attached to the pteridine part of the molecule. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (Fig. 8.12).

Figure 8.14 Folic acid structure. This is formed from three building blocks as shown. Tetrahydrofolate has additional hydrogen atoms at positions 5, 6, 7 and 8.

Table 8.5 Causes of folate deficiency

Nutritional (major cause)	Excess utilization
Poor intake	Physiological
Old age	Pregnancy
Poor social conditions	Lactation
Starvation	Prematurity
Alcohol excess (also causes impaired utilization)	Pathological
Poor intake due to anorexia	Haematological disease with excess red cell production, e.g. haemolysis
Gastrointestinal disease, e.g. partial gastrectomy, coeliac disease, Crohn's disease	Malignant disease with increased cell turnover
Cancer	Inflammatory disease
Antifolate drugs	Metabolic disease, e.g. homocystinuria
Anticonvulsants:	Haemodialysis or peritoneal dialysis
Phenytoin	Malabsorption
Primidone	Occurs in small bowel disease, but the effect is minor compared with that of anorexia
Methotrexate	
Pyrimethamine	
Trimethoprim	

Dietary intake

Folate is found in green vegetables, such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60–90% of the folate. The minimal daily requirement is about 100 µg.

Folate deficiency

The causes of folate deficiency are shown in Table 8.5. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The body's reserves of folate, unlike vitamin B₁₂, are low (about 10 mg). On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g. patients in intensive care units).

There is no simple relationship between maternal folate status and fetal abnormalities but folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. In the USA and Canada, mandatory fortification of grain products, e.g. bread, flour and rice, has substantially improved folate status and has been associated with a significant fall in neural tube defects.

Clinical features

Patients with folate deficiency may be asymptomatic or present with symptoms of anaemia or of the underlying cause. Glossitis can occur. Unlike with B₁₂ deficiency, neuropathy does not occur.

Investigations

The haematological findings are those of a megaloblastic anaemia as discussed on page 382.

Blood measurements

Serum and red cell folate are assayed by radioisotope dilution or immunological methods. Normal levels of serum folate are 4–18 µg/L (5–63 nmol/L). The amount of folate in the red cells is a better measure of tissue folate; the normal range is 160–640 µg/L.

Further investigations

In many cases of folate deficiency, the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate investigations, such as small bowel biopsy, should be performed.

Treatment and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. Blood transfusion is not indicated in chronic anaemia; indeed, it is dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B₁₂ deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B₁₂ level is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B₁₂ while awaiting serum levels.

Treatment of vitamin B₁₂ deficiency

Hydroxocobalamin 1000 µg can be given intramuscularly to a total of 5–6 mg over the course of 3 weeks; 1000 µg is then necessary every 3 months for the rest of the patient's life. Alternatively, oral B₁₂ 2 mg/day is used, as 1–2% of an oral dose is absorbed by diffusion and therefore does not require intrinsic factor.

Compliance with an oral daily regimen may be a problem, particularly in elderly patients. The use of sublingual nuggets of B₁₂ (2 × 1000 µg daily) has been suggested to be an effective and more convenient option.

Clinical improvement may occur within 48 hours and a reticulocytosis can be seen some 2–3 days after starting therapy, peaking at 5–7 days. Improvement of the polyneuropathy may occur over 6–12 months, but longstanding spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B₁₂ should be monitored; if low levels occur, prophylactic vitamin B₁₂ should be given. Vegans may require B₁₂ supplements.

Treatment of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily; the same haematological response occurs as seen after treatment of vitamin B₁₂ deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, e.g. coeliac disease, should be treated.

Prophylactic folic acid (400 µg daily) is recommended for all women planning a pregnancy to reduce neural tube defects. Many authorities also recommend prophylactic administration of folate throughout pregnancy.

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid is also given in chronic haematological disorders where there is rapid cell turnover.

Macrocytosis without megaloblastic changes

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common *physiological* cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn. Common *pathological* causes are:

- Alcohol excess
- Liver disease
- Reticulocytosis
- Hypothyroidism
- Some haematological disorders (e.g. aplastic anaemia, sideroblastic anaemia, pure red cell aplasia)
- Drugs (e.g. hydroxycarbamide, azathioprine)
- Cold agglutinins due to autoagglutination of red cells (see p. 398) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal levels of vitamin B₁₂ and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes also leads to a raised MCV because they are large cells.

A high alcohol consumption is a frequent cause of a raised MCV, and in such patients the MCV can be used as a surrogate marker for monitoring excessive alcohol consumption. A full blown megaloblastic anaemia can also occur in people who use alcohol to excess; this is due to a toxic effect of alcohol on erythropoiesis and/or to dietary folate deficiency.

ANAEMIA DUE TO MARROW FAILURE (APLASTIC ANAEMIA)

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is usually an acquired condition but may rarely be inherited.

Aplastic anaemia is due to a reduction in the number of pluripotent stem cells (Fig. 8.1) together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloblastic leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

Causes

A list of causes of aplasia is given in Table 8.6. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, ribavirin, tolbutamide, non-steroidal anti-inflammatory agents, and many others which have been reported to cause occasional cases of aplasia.

Inherited aplastic anaemias are rare. Multiple gene mutations have been identified. Several are tumour suppressor

genes and have been seen in one-third of aplastic anaemias. Fanconi's anaemia is inherited as an autosomal recessive and is associated with skeletal, skin, eye, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years.

Clinical features

The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising with minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

Investigations

- Pancytopenia
- The virtual absence of reticulocytes
- A hypocellular or aplastic bone marrow with increased fat spaces (Fig. 8.15).

Anaemia due to marrow failure (aplastic anaemia)

Overwhelming sepsis

Differential diagnosis

This is from other causes of pancytopenia (Table 8.7). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

Treatment and prognosis

The treatment of aplastic anaemia depends on providing supportive care while awaiting bone marrow recovery and specific treatment to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also p. 448). Any suspicion of infection in a severely neutropenic patient should lead to immediate institution of broad-spectrum parenteral antibiotics. Supportive care including transfusions of red cells and platelets should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes, platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:

- Neutrophil count of $<0.5 \times 10^9/L$
- Platelet count of $<20 \times 10^9/L$
- Reticulocyte count of $<40 \times 10^9/L$.

Bone marrow transplantation is the treatment of choice for patients under the age of 40 with an HLA-identical sibling donor, where it gives a 75–90% chance of long-term survival.

Immunosuppressive therapy is recommended for:

- Patients with severe disease over the age of 40
- Younger patients with severe disease without an HLA-identical sibling donor
- Patients who do not have severe disease but who are transfusion-dependent.

The standard immunosuppressive treatment is antithymocyte globulin (ATG) and ciclosporin, which results in response rates of 60–80% with 5-year survival rates of 75–85%.

Bone marrow transplantation using matched unrelated donors is an option for patients under the age of 50 who have no matched sibling donor, and who have failed to respond to immunosuppression with ATG and ciclosporin, and the results are improving (5-year survival of 65–73%). The main problems are graft rejection, graft-versus-host disease and viral infections.

Levels of haemopoietic growth factors (Fig. 8.1) are normal or increased in most patients with aplastic anaemia, and are ineffective as primary treatment.

Steroids should not be used to treat severe aplastic anaemia except for serum sickness due to ATG. They are also used to treat children with congenital pure red cell aplasia (Diamond–Blackfan syndrome).

Adult pure red cell aplasia is associated with a thymoma in 5–15% of cases and thymectomy occasionally induces a remission. It may also be associated with autoimmune disease or be idiopathic. Steroids, cyclophosphamide, azathioprine and ciclosporin are effective treatment in some cases.

HAEMOLYTIC ANAEMIAS: AN INTRODUCTION

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (Fig. 8.5).

Consequences of haemolysis (Fig. 8.16)

Shortening of red cell survival does not always cause anaemia as there is a compensatory increase in red cell production by the bone marrow. If the red cell loss can be contained within the marrow's capacity for increased output, then a haemolytic state can exist without anaemia (*compensated haemolytic disease*). The bone marrow can increase its output by six to eight times by increasing the proportion of cells committed to erythropoiesis (*erythroid hyperplasia*) and by expanding the volume of active marrow. In addition, immature red cells (*reticulocytes*) are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (the description of this appearance on the blood film is *polychromasia*) due to the presence of residual ribosomal RNA. Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supravital stain for residual RNA (e.g. new methylene blue).

Sites of haemolysis

Extravascular haemolysis

In most haemolytic conditions red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis

When red cells are rapidly destroyed within the circulation, haemoglobin is liberated (Fig. 8.17). This is initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma haemoglobin is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, haemoglobin is broken down and becomes deposited in the cells as *haemosiderin*. This can be detected in the spun sediment of urine using Perls' reaction. Some of the free plasma haemoglobin is oxidized to *methaemoglobin*, which dissociates into *ferrihaem* and globin. *Plasma haemopexin* binds ferrihaem; but if its binding capacity is exceeded,

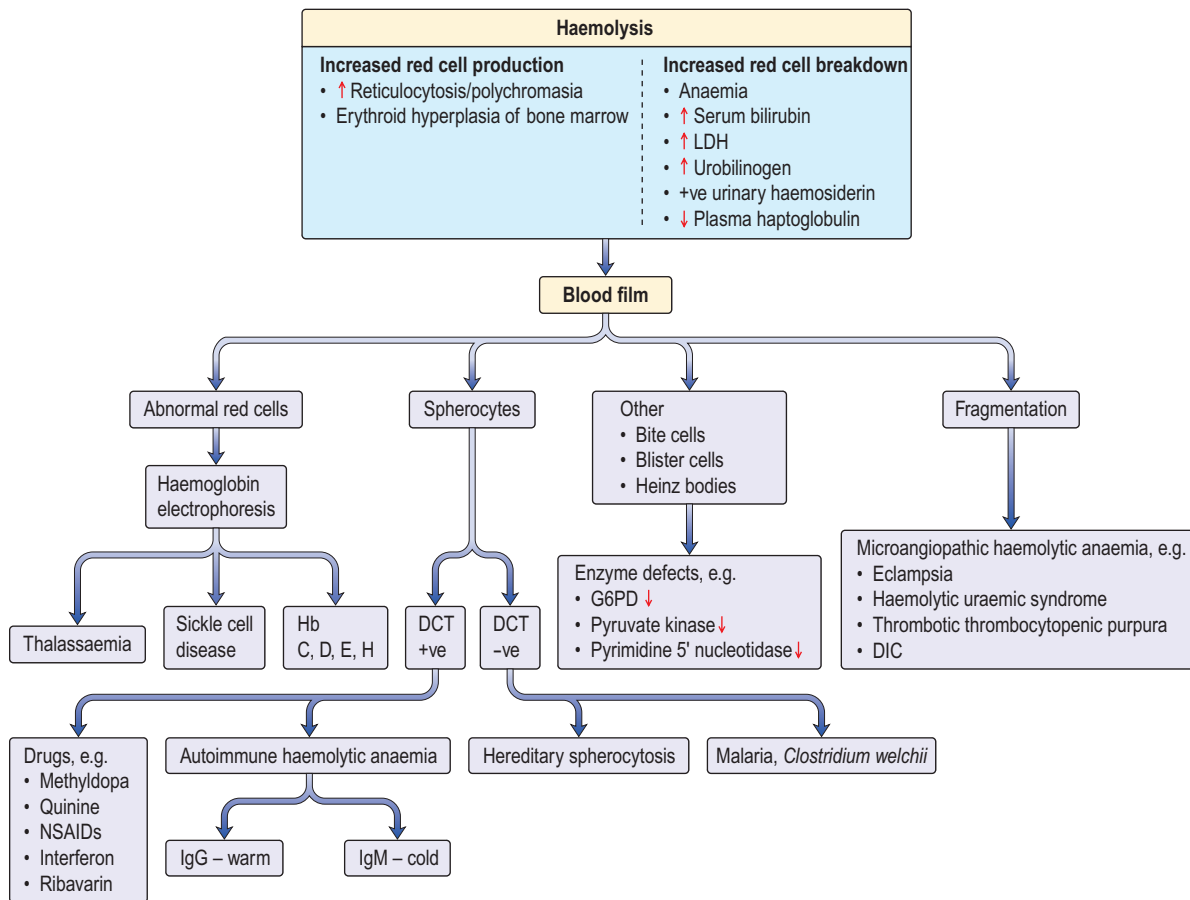

Figure 8.16 Haemolysis: diagnostic and haematological features. DCT, direct Coombs' test; G6PD, glucose-6-phosphate dehydrogenase; LDH, lactate dehydrogenase.

Figure 8.17 The fate of haemoglobin in the plasma following intravascular haemolysis.

ferrihaem becomes attached to albumin, forming *methaemalbumin*. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of Schumm's test.

The liver plays a major role in removing haemoglobin bound to haptoglobin and haemopexin and any remaining free haemoglobin.

Evidence for haemolysis

Increased red cell breakdown is accompanied by increased red cell production. This is shown in Figure 8.16.

Demonstration of shortened red cell lifespan

Red cell survival can be estimated from ^{51}Cr -labelled red cells given intravenously but is rarely performed.

Intravascular haemolysis

This is suggested by raised levels of plasma haemoglobin, haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm's test).

Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Table 8.8.

INHERITED HAEMOLYTIC ANAEMIA

Red cell membrane defects

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (Fig. 8.18).

Hereditary spherocytosis (HS)

HS is the most common inherited haemolytic anaemia in northern Europeans, affecting 1 in 5000. It is inherited in an autosomal dominant manner, but in 25% of patients, neither parent is affected and it is presumed that HS has occurred by spontaneous mutation or is truly recessive. HS is due to defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 8.18), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells which is dependent on ATP produced by glycolysis. The surface-to-volume ratio decreases, and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation so they have a shortened lifespan.

Clinical features

The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years and some patients may go through life with no symptoms and

Figure 8.18 Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red cell membrane showing the sites of the principal defects. Vertical interactions producing HS: (a) ankyrin mutation, HS (Ank+) producing deficiency (45% of cases); (b) HS band 3 deficiency (20%); (c) β spectrin deficiency, HS (Sp+) (<20%); (d) abnormal spectrin/protein 4.1 binding, HS (Sp-4.1); (e) protein 4.2 (pallidin) deficiency (Japanese). These produce various autosomal dominant and recessive forms of the disease. Horizontal interactions producing HE: α spectrin (80%), protein 4.1 (15%), β spectrin (5%).

Figure 8.19 Spherocytes (arrowed). This blood film also shows reticulocytes, polychromasia and a nucleated erythroblast.

are detected only during family studies. The patient may eventually develop anaemia, splenomegaly and ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with erythro (parvo) virus, whereas megaloblastic anaemia is the result of folate depletion owing to the hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see p. 351).

Investigations

- **Anaemia.** This is usually mild, but occasionally can be severe.
- **Blood film.** This shows spherocytes (Fig. 8.19) and reticulocytes.
- **Haemolysis** is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).
- **Osmotic fragility.** When red cells are placed in solutions of increasing hypotonicity, they take in water, swell, and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice, but may be useful to confirm a suspicion of spherocytosis on a blood film.
- **Direct antiglobulin (Coombs') test** is negative in hereditary spherocytosis, virtually ruling out autoimmune haemolytic anaemia where spherocytes are also commonly present.

Treatment

Splenectomy is indicated in hereditary spherocytosis to relieve symptoms due to anaemia or splenomegaly, reverse growth failure and prevent recurrent gallstones. It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 406). Splenectomy should be preceded by appropriate immunization and followed by lifelong penicillin prophylaxis (see Box 8.3). In addition to the well known risk of bacterial infection, there is also some evidence that there is a significant risk of adverse arterial and venous thromboembolic events after splenectomy performed for hereditary spherocytosis.

Following splenectomy, the spherocytes persist but the Hb usually returns to normal as the red cells are no longer destroyed.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are elliptical due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex

Figure 8.20 Normal development switches in globin expression. (a) Sites of haemopoiesis and globin changes at various gestational ages. (b) Structure of α -like and β -like globin gene clusters. LCR, locus control region; HS, major upstream regulatory element. (From Higgs DR, Engel JD, Stamatoyannopoulos G. *Thalassaemia*. Lancet 2012; 379:373–383, with permission.)

which leads to weakness of the horizontal protein interaction and to the membrane defect (Fig. 8.18). Clinically it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional patients require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood.

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required since splenectomy is contraindicated as it may result in fatal thromboembolic events.

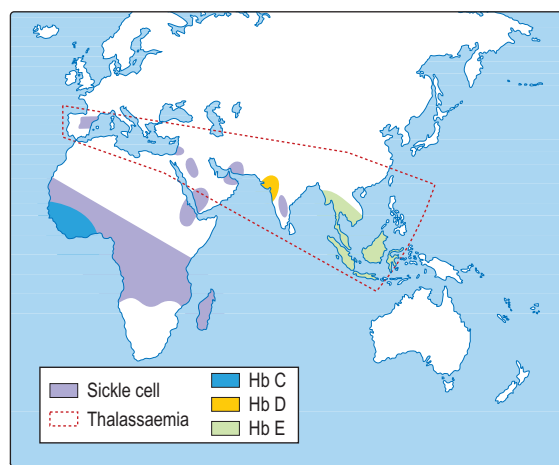

Haemoglobin abnormalities

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate. Later, fetal haemoglobin (HbF), which has two α and two γ chains, is produced (Fig. 8.20). There is increasing synthesis of β chains from 13 weeks' gestation and at term there is 80% HbF and 20% HbA. The haemoglobin switch from HbF to HbA occurs after birth when the genes for γ chain production are further suppressed and there is rapid increase in the synthesis of β chains. BCL IIA, a zinc finger protein, is one of a number of proteins that suppress γ gene expression. There is little HbF produced (normally <1%) from 6 months after birth. The δ chain is synthesized just before birth and HbA₂ ($\alpha_2\delta_2$) remains at a level of about 2% throughout adult life (Table 8.9).

Globin chains are synthesized in the same way as any protein (see p. 42). A normal individual has four α -globin chain genes (Fig. 8.20) with two α -globin genes on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ϵ , γ , δ and β chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal haemoglobin synthesis is discussed on page 374.

Table 8.9 Some types of haemoglobin

	Haemoglobin	Structure	Comment
Normal	A	$\alpha_2\beta_2$	Comprises 97% of adult haemoglobin
	A ₂	$\alpha_2\delta_2$	Comprises 2% of adult haemoglobin Elevated in β -thalassaemia
	F	$\alpha_2\gamma_2$	Normal haemoglobin in fetus from 3rd to 9th month Increased in β -thalassaemia Comprises <1% of haemoglobin in adult
Abnormal chain production	H	β_4	Found in α -thalassaemia Biologically useless
	Barts	γ_4	Comprises 100% of haemoglobin in homozygous α -thalassaemia Biologically useless
Abnormal chain structure	S	$\alpha_2\beta_2^S$	Substitution of valine for glutamine acid in position 6 of β chain
	C	$\alpha_2\beta_2^C$	Substitution of lysine for glutamic acid in position 6 of β chain

Forget BG. Progress in understanding the hemoglobin switch. *New England Journal of Medicine* 2011; 365:852–854.

Haemoglobinopathies

Abnormalities occur in:

- Globin chain production (e.g. thalassaemia)
- Structure of the globin chain (e.g. sickle cell disease)
- Combined defects of globin chain production and structure, e.g. sickle cell β -thalassaemia.

The thalassaemias

The thalassaemias affect people throughout the world (Fig. 8.21). Normally, there is balanced (1:1) production of α and β chains. The defective synthesis of globin chains in thalassaemia leads to 'imbalanced' globin chain production, leading to precipitation of globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis.

 β -Thalassaemia

In *homozygous* β -thalassaemia, either no normal β chains are produced (β^0) or β -chain production is very reduced (β^+). There is an excess of α chains, which precipitate in erythroblasts and red cells causing ineffective erythropoiesis and haemolysis. The excess α chains combine with whatever β , δ and γ chains are produced, resulting in increased quantities of HbA₂ and HbF and, at best, small amounts of HbA. In heterozygous β -thalassaemia there is usually symptomless microcytosis with or without mild anaemia. Table 8.10 shows

Table 8.10 β -Thalassaemia: common findings

Type of thalassaemia	Findings in homozygote	Findings in heterozygote
β^+	Thalassaemia major HbA + F + A ₂	Thalassaemia minor HbA ₂ raised
β^0	Thalassaemia major HbF + A ₂	Thalassaemia minor HbA ₂ raised
$\delta\beta$	Thalassaemia intermedia HbF only	Thalassaemia minor HbF 5–15% HbA ₂ normal
$\delta\beta^+$ (Lepore)	Thalassaemia major or intermedia HbF and Lepore	Thalassaemia minor Hb Lepore 5–15% HbA ₂ normal

Hb Lepore is a cross-fusion product of δ and β globin genes.

the findings in the homozygote and heterozygote for the common types of β -thalassaemia.

Molecular genetics

The molecular errors accounting for over 200 genetic defects leading to β -thalassaemia have been characterized. Unlike in α -thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable β -globin, which cannot be utilized.

Clinical syndromes

Clinically, β -thalassaemia can be divided into the following:

- Thalassaemia minor (or trait), the symptomless heterozygous carrier state
- Thalassaemia intermedia, a moderate anaemia, not requiring regular transfusions (with a number of different genotypes)
- Thalassaemia major (generally homozygous β -thalassaemia), severe anaemia requiring regular transfusions.

Thalassaemia minor (trait)

This common carrier state (heterozygous β -thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcytic with a low MCV and MCH, and

it may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (Table 8.2). The RDW is usually normal (see p. 373). Hb electrophoresis usually shows a raised HbA₂ and often a raised HbF (Fig. 8.22). Iron should not be given to these patients unless they also have proven coincidental iron deficiency.

Thalassaemia intermedia

Thalassaemia intermedia includes patients who are symptomatic with moderate anaemia (Hb 70–100 g/L), who do not require regular transfusions.

Thalassaemia intermedia may be due to a combination of homozygous mild β^+ - and α -thalassaemia, where there is reduced α -chain precipitation and less ineffective erythropoiesis and haemolysis. The inheritance of hereditary persistence of HbF with homozygous β -thalassaemia also results in a milder clinical picture than unmodified β -thalassaemia major because the excess α chains are partially removed by the increased production of γ chains.

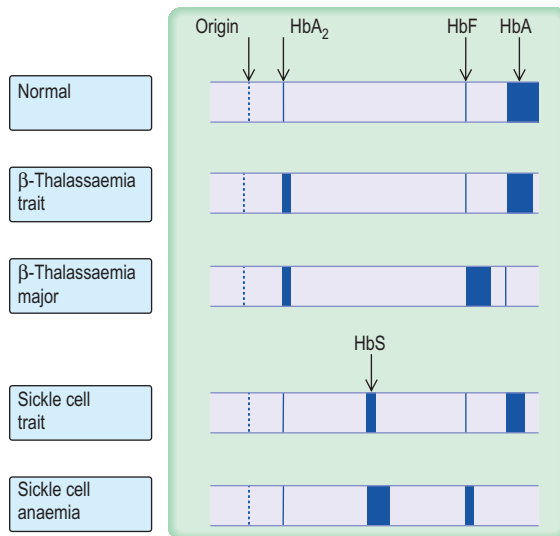

Figure 8.22 Patterns of haemoglobin electrophoresis.

Patients may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones and infections are also seen. It should be noted that these patients may be iron overloaded despite a lack of regular blood transfusions. This is caused by excessive iron absorption which results from the underlying dyserythropoiesis (see iron absorption, p. 377).

Thalassaemia major (Cooley's anaemia)

Most children affected by homozygous β -thalassaemia present during the first year of life with:

- Failure to thrive and recurrent bacterial infections
- Severe anaemia from 3 to 6 months when the switch from γ - to β -chain production should normally occur
- Extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 8.23a).

Skull X-rays in these children show the characteristic 'hair on end' appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 8.23b). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 8.23c).

The classic features of untreated thalassaemia major are generally only observed in patients from countries without good blood transfusion support.

Management

The aims of treatment are to suppress ineffective erythropoiesis, prevent bony deformities and allow normal activity and development.

- **Long-term folic acid** supplements are required.
- **Regular transfusions** should be given to keep the Hb above 100 g/L. Blood transfusions may be required every 4–6 weeks.
- If **transfusion requirements** increase, splenectomy may help, although this is usually delayed until after the age of 6 years because of the risk of infection. Prophylaxis against infection is required for patients undergoing splenectomy (see p. 406).
- **Iron overload** caused by repeated transfusions (transfusion haemosiderosis) may lead to damage to the

endocrine glands, liver, pancreas and the myocardium by the time patients reach adolescence. Magnetic resonance imaging (myocardial T₂-relaxation time) is useful for monitoring iron overload in thalassaemia; both the heart and the liver can be monitored. The standard iron-chelating agent remains desferrioxamine, although it has to be administered parenterally. Desferrioxamine is given as an overnight subcutaneous infusion on 5–7 nights each week. Ascorbic acid 200 mg daily is given, as it increases the urinary excretion of iron in response to desferrioxamine. Often young children have a very high standard of chelation as it is organized by their parents. However, when the children become adults and take on this role themselves they often rebel and chelation with desferrioxamine may become problematic. Deferiprone, an oral iron chelator, has been available for some years, and results on a new once-daily oral iron chelator, deferasirox, indicate that it is safe, similar in effectiveness to desferrioxamine and is being increasingly used.

- **Intensive treatment with desferrioxamine** has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage and nerve deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring the serum ferritin and by assessment of hepatic iron stores by MRI.
- **Bone marrow transplantation** has been used in young patients with HLA-matched siblings. It has been successful in patients in good clinical condition with a 3-year mortality of <5%, but there is a high mortality (>50%) in patients in poor condition with iron overload and liver dysfunction.
- **Prenatal diagnosis and gene therapy** are discussed on page 43.
- **Patients' partners should be tested.** If both partners have β -thalassaemia trait, there is a one in four chance of such pregnancy resulting in a child having β -thalassaemia major. Therefore, couples in this situation must be offered prenatal diagnosis (see p. 43).

α -Thalassaemia

Molecular genetics

In contrast to β -thalassaemia, α -thalassaemia is often caused by gene deletions, although mutations of the α -globin genes may also occur. The gene for α -globin chains is duplicated on both chromosomes 16, i.e. a normal person has a total of four α -globin genes. Deletion of one α -chain gene (α^+) or both α -chain genes (α^0) on each chromosome 16 may occur (Table 8.11). The former is the most common of these abnormalities.

- **Four-gene deletion** (deletion of both genes on both chromosomes); there is no α -chain synthesis and only Hb Barts (γ_4) is present. Hb Barts cannot carry oxygen and is incompatible with life (Table 8.9 and Table 8.11). Infants are either stillborn at 28–40 weeks or die very shortly after birth. They are pale, oedematous and have enormous livers and spleens – a condition called hydrops fetalis.
- **Three-gene deletion;** HbH disease, which is common in parts of Asia, has four β chains with low levels of HbA and Hb Barts. HbA₂ is normal or reduced. HbH does not transport oxygen and precipitates in erythroblasts

Table 8.11 The α -thalassaemias

Number α -globin genes deleted	Genotype	Haemoglobin type	Clinical picture
4	—/—	Hb Barts (α_4)	Hydrops fetalis
3	—/— α	HbH (α_4)	Moderately severe anaemia Splenomegaly
2	— α /— α or —/ $\alpha\alpha$	HbA Some HbH bodies	Mild anaemia
1	$\alpha\alpha$ /— α	HbA	Very mild anaemia or no anaemia

The normal α -globin genotype is $\alpha\alpha/\alpha\alpha$ (i.e. 4 α -globin genes present).

and erythrocytes. There is moderate anaemia (Hb 70–100 g/L) and splenomegaly (thalassaemia intermedia). The patients are not usually transfusion-dependent.

- **Two-gene deletion** (α -thalassaemia trait); there is microcytosis with or without mild anaemia. HbH bodies may be seen on staining a blood film with brilliant cresyl blue.
- **One-gene deletion;** the blood picture is usually normal.

Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α -thalassaemia trait.

Less commonly, α -thalassaemia may result from genetic defects other than deletions, for example mutations in the stop codon producing an α chain with many extra amino acids (Hb Constant Spring). It has a more severe clinical course than HbH with severe anaemia often precipitated by infection.

Sickle syndromes

Sickle cell haemoglobin (HbS) results from a single-base mutation of adenine to thymine, which produces a substitution of valine for glutamic acid at the sixth codon of the β -globin chain ($\alpha_2\beta_2^{\text{Glu} \rightarrow \text{Val}}$). In the homozygous state (*sickle cell anaemia*), both genes are abnormal (HbSS), whereas in the heterozygous state (sickle cell trait, HbAS) only one chromosome carries the gene. As the synthesis of HbF is normal, the disease usually does not manifest itself until the HbF decreases to adult levels at about 6 months of age.

The sickle gene is commonest in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East and Southern Europe.

Pathogenesis

Deoxygenated HbS molecules are insoluble and polymerize. The flexibility of the cells is decreased and they become rigid and take up their characteristic sickle appearance (Fig. 8.24). This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via calcium activated potassium channels called the Gados channel. These irreversibly sickled cells are dehydrated and dense and will not return to normal when oxygenated. Sickling can produce:

Figure 8.24 Sickle cells (arrowed) and target cells.

- a shortened red cell survival
- impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.

Sickling is precipitated by infection, dehydration, cold, acidosis or hypoxia. In many cases, the cause is unknown, but adhesion proteins on activated endothelial cells (VCAM-1) may play a causal role, particularly in vaso-occlusion when rigid cells are trapped, facilitating polymerization. HbS releases its oxygen to the tissues more easily than does normal Hb, and patients therefore feel well despite being anaemic (except of course during crises or complications).

Depending on the type of haemoglobin chain combinations, three clinical syndromes occur:

- Homozygous HbSS have the most severe disease
- Combined heterozygosity (HbSC) for HbS and C (see below) who suffer intermediate symptoms
- Heterozygous HbAS (sickle cell trait) have no symptoms (see p. 395).

Sickle cell anaemia

Clinical features

Vaso-occlusive crises

An early presentation may be acute pain in the hands and feet (dactylitis) owing to vaso-occlusion of the small vessels. Severe pain in other bones, e.g. femur, humerus, vertebrae, ribs, pelvis, occurs in older children/adults. These attacks vary greatly in frequency from patient to patient and sometimes in the same patient from year to year; however, as a generalization, a patient with moderately severe sickle cell anaemia may have around three hospital admissions a year from painful vaso-occlusive crises. Fever often accompanies the pain.

Pulmonary hypertension

Pulmonary hypertension is a known consequence of sickle cell anaemia, occurring in 30–40% of patients, and is associated with an increased mortality. The 'hyperhaemolytic paradigm' (HHP) proposes that haemolysis in sickle cell disease leads to increased cell-free plasma Hb, which consumes NO, leading to a state of NO deficiency, endothelial dysfunction and a high prevalence of pulmonary hypertension. The basis of the HHP has recently been questioned.

Acute chest syndrome

This occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the commonest causes of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow or pulmonary infarction due to sequestration of sickle cells. It comprises shortness of breath, chest pain, hypoxia and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, leading to death in a few

hours. Management is with pain relief, high-flow supplemental oxygen and antibiotics (cefotaxime and clarithromycin), which should be started immediately. Exchange transfusion will reduce the amount of HbS to <20% if there is no improvement. Ventilation (CPAP) may be necessary. Infections can be due to *Chlamydia* and mycoplasma, as well as *Streptococcus pneumoniae*.

Anaemia

Chronic haemolysis produces a stable haemoglobin level, usually in the 60–80 g/L range, but an acute fall in the haemoglobin level can occur owing to:

- Splenic sequestration
- Bone marrow aplasia
- Further haemolysis due to drugs, acute infection or associated G6PD deficiency.

Splenic sequestration

Vaso-occlusion produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading in some to circulatory collapse and death. The condition occurs in childhood before multiple infarctions have occurred. The latter eventually leads to a fibrotic non-functioning spleen. Liver sequestration can also occur.

Bone marrow aplasia

This most commonly occurs following infection with erythrovirus B₁₉, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood, because of the failure of erythropoiesis in the marrow.

Long-term problems

Growth and development. Young children are short but regain their height by adulthood. However, they remain below the normal weight. There is often delayed sexual maturation, which may require hormone therapy.

Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips, shoulders, compression of vertebrae and shortening of bones in the hands and feet occur. These episodes are the common cause for the painful crisis. Osteomyelitis is commoner in sickle cell disease and is caused by *Staphylococcus aureus*, *Staph. pneumoniae* and salmonella (see p. 534). Occasionally, hip joint replacement may be required.

Infections are common in tissues susceptible to vasoocclusion, e.g. bones, lungs, kidneys.

Leg ulcers occur spontaneously (vaso-occlusive episodes) or following trauma and are usually over the medial or lateral malleoli. They often become infected and are quite resistant to treatment, sometimes blood transfusion may facilitate ulcer healing.

Cardiac problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions occur due to thrombotic episodes which are not secondary to atheroma.

Neurological complications occur in 25% of patients, with transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. Strokes occur in about 11% of patients under 20 years of age. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. About 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have very high risk of stroke. It has now been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler

FURTHER READING

Bunn HF, Nathan DG, Dover GJ. Pulmonary hypertension and nitric oxide depletion in sickle cell disease. *Blood* 2010; 116:687–692.

ultrasonography, are maintained on a regular programme of transfusion that is designed to suppress erythropoiesis so that no more than 30% of the circulating red cells are their own, about 90% of strokes in such children could be prevented.

Cholelithiasis. Pigment stones occur as a result of chronic haemolysis.

Liver. Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

Renal. Chronic tubulointerstitial nephritis occurs (see p. 596).

Priapism. An unwanted painful erection occurs from vaso-occlusion and can be recurrent. This may result in impotence. Treatment is with an α -adrenergic blocking drug, analgesia and hydration.

Eye. Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

Pregnancy. Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother.

Investigations

- **Blood count.** The level of Hb is in the range 60–80 g/L with a high reticulocyte count (10–20%).
- **Blood films** can show features of hyposplenism (see Fig. 8.29) and sickling (Fig. 8.24).
- **Sickle solubility test.** A mixture of HbS in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of HbS, whereas normal Hb gives a clear solution. A number of commercial kits such as Sickledex are available for rapid screening for the presence of HbS, e.g. before surgery in appropriate ethnic groups and in the A&E department.
- **Hb electrophoresis** (Fig. 8.22) is always needed to confirm the diagnosis. There is no HbA, 80–95% HbSS and 2–20% HbF.
- **The parents** of the affected child will show features of sickle cell trait.

Management

Precipitating factors (see above) should be avoided or treated quickly. The complications requiring inpatient management are shown in Table 8.12.

Acute painful attacks require supportive therapy with intravenous fluids, and adequate analgesia. Oxygen and antibiotics are only given if specifically indicated. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs (Box 8.1).

Prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal and *Haemophilus influenzae* type b vaccine (see p. 406). Folic acid is given to all patients with haemolysis.

Anaemia

Blood transfusions should only be given for clear indications. Patients with steady state anaemia, those having minor surgery or having painful episodes without complications should not be transfused. Transfusions should be given for heart failure, TIAs, strokes, acute chest syndrome, acute splenic sequestration and aplastic crises. Before elective operations and during pregnancy, repeated transfusions may

Priapism

Box 8.1 Management of acute painful crisis in opioid naive adults with sickle cell disease

Morphine/diamorphine

- 0.1 mg/kg i.v./s.c. every 20 min until pain controlled, then
- 0.05–0.1 mg/kg i.v./s.c. (or oral morphine) every 2–4 h

Patient-controlled analgesia (PCA) (example for adults >50 kg)

Diamorphine/Morphine

- Continuous infusion: 0–10 mg/h
- PCA bolus dose: 2–10 mg
- Dose duration: 1 min
- Lockout time: 20–30 min

Adjuvant oral analgesia

- Paracetamol 1 g 6-hourly
- ± Ibuprofen^a 400 mg 8-hourly
- Or diclofenac^a 50 mg 8-hourly

Laxatives (all patients)

For example:

- Lactulose 10 mL × 2 daily
- Senna 2–4 tablets daily
- Sodium docusate 100 mg × 2 daily
- Macrogol 1 sachet daily
- Lubiprostone

Other adjuvants

Anti-pruritics

- Hydroxyzine 25 mg × 2 as required

Antiemetics

- Prochlorperazine 5–10 mg × 3 as required
- Cyclizine 50 mg × 3 as required

Anxiolytic

- Haloperidol 1–3 mg oral/i.m. × 2 as required

^aCaution advised with NSAIDs in renal impairment. (Adapted from Rees DC, Olujuhungbe AD, Parker NE et al. Guidelines for the management of the acute painful crisis in sickle cell disease. British Journal of Haematology 2003; 120(5):744–752.)

be used to reduce the proportion of circulating HbS to <20% to prevent sickling. Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Transfusion and splenectomy may be life-saving for young children with splenic sequestration. A full blood crossmatching compatibility screen should always be performed.

Hydroxycarbamide (hydroxyurea) is the first drug which has been widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing HbF concentrations. Hydroxycarbamide has been shown in trials to reduce the episodes of pain, the acute chest syndrome, and the need for blood transfusions.

Inhaled nitric oxide is a new approach to the treatment of painful crises in sickle cell anaemia based on the hyper-haemolytic paradigm discussed briefly above. However, it is yet to become an established therapy based on randomized controlled trials.

Stem cell transplantation has been used to treat sickle cell anaemia although in fewer numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome or refractory pain) and have an HLA-matched donor are the best candidates for transplantation.

Counselling

A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues, drug and birth control.

Prognosis

Some patients with HbSS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in the severity of the disease and some patients have a relatively normal lifespan with few complications.

Sickle cell trait

These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in non-pressurized aircraft. Sickle cell trait gives some protection against *Plasmodium falciparum* malaria (see p. 144), and consequently the sickle gene has been seen as an example of a balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). Typically there is 60% HbA and 40% HbS. It should be emphasized that unlike thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or by Hb electrophoresis (Fig. 8.22).

Other structural globin chain defects

There are very many Hb variants and most are not associated with any clinical manifestations. However, some Hb variants may interact with HbS, e.g. compound heterozygosity for HbC and HbS gives rise to HbSC disease. The clinical course of HbSC disease is generally somewhat milder than that of HbSS disease, but there is an increased likelihood of thrombosis, which may lead to thrombosis in pregnancy and to retinopathy.

Combined defects of globin chain production and structure

Abnormalities of Hb structure (e.g. HbS, C) can occur in combination with thalassaemia. The combination of β -thalassaemia trait and sickle cell trait (sickle cell β -thalassaemia) resembles sickle cell anaemia (HbSS) clinically.

HbE ($\alpha_2\beta_2^{26\text{Glu} \rightarrow \text{lys}}$) is the most common Hb variant in South-east Asia, and the second most prevalent haemoglobin variant worldwide. HbE heterozygotes are asymptomatic; the haemoglobin level is normal, but red cells are microcytic. Homozygous HbE causes a mild microcytic anaemia, but the combination of heterozygosity for HbE and β -thalassaemia produces a variable anaemia, which can be as severe as β -thalassaemia major.

Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either β -thalassaemia or sickle cell trait, 25% will have β -thalassaemia major or sickle cell anaemia, respectively. Recognition of these heterozygous states in parents and family counselling provide a basis for antenatal screening and diagnosis (p. 44).

Prognosis

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. β -Thalassaemia trait can always be detected by a low MCV and MCH and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory need a specific request to screen for sickle cell trait. Clearly, universal antenatal screening as practised in the UK avoids such problems.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected as there is a risk of a severe fetal Hb defect, particularly β -thalassaemia major. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Abortion is offered if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second trimester abortions.

Metabolic disorders of the red cell

Red cell metabolism

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for the maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential that Hb be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power are (Fig. 8.25):

- The glycolytic (Embden–Meyerhof) pathway, in which glucose is metabolized to pyruvate and lactic acid with production of ATP
- The hexose monophosphate (pentose phosphate) pathway, which provides reducing power for the red cell in the form of NADPH.

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- Rigidity due to cross-linking of spectrin, which decreases membrane flexibility (see Fig. 8.18) and causes 'leakiness' of the red cell membrane
- Oxidation of the Hb molecule, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

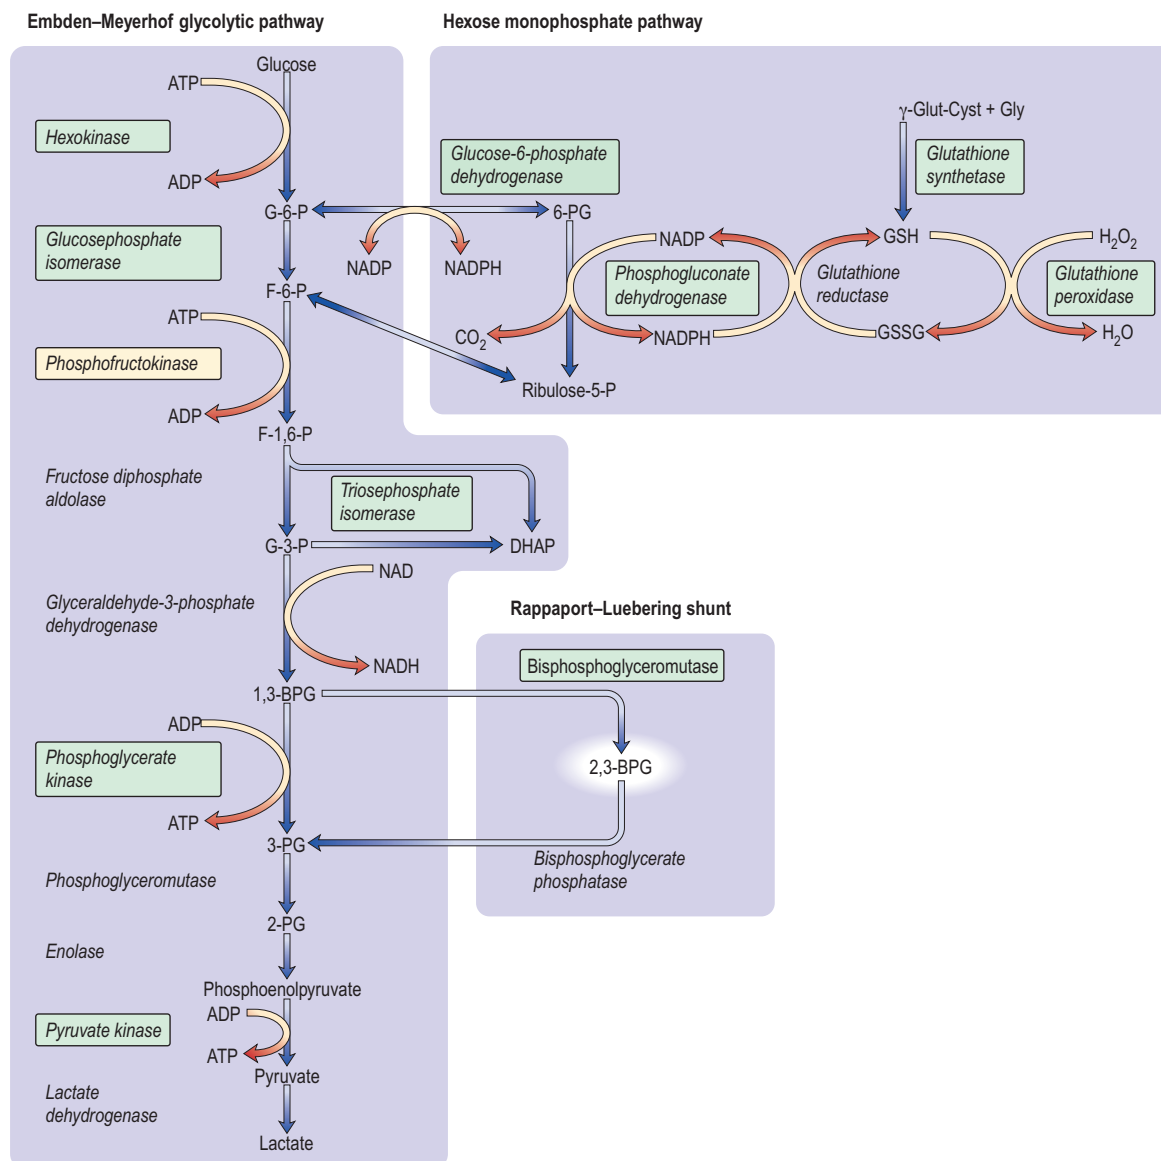

Figure 8.25 Glucose metabolism pathways in red cells. The enzymes in green boxes indicate documented hereditary deficiency diseases. BPG, bisphosphoglycerate; DHAP, dihydroxyacetone phosphate; F, fructose; G, glucose; GSSG, oxidized glutathione; GSH, reduced glutathione; P, phosphate; PG, phosphoglycerate.

2,3-BPG is formed from a side-arm of the glycolytic pathway (Fig. 8.25). It binds to the central part of the Hb tetramer, fixing it in the low-affinity state (Fig. 8.4). A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues.

In addition to the G6PD, pyruvate kinase and pyrimidine 5' nucleotidase deficiencies described below, there are a number of rare enzyme deficiencies that need specialist investigation.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

The enzyme G6PD holds a vital position in the hexose monophosphate shunt (Fig. 8.25), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells where it is the only source of NADPH, which is used via glutathione to

protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particularly in Africa, around the Mediterranean, the Middle East (around 20%) and South-east Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is more common in males than in females. However, female heterozygotes can also have clinical problems due to lyonization, whereby because of random X-chromosome inactivation female heterozygotes have two populations of red cells – a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD, and mutations are mostly single amino acid substitutions (missense point mutations). WHO has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common types with normal activity are called type B⁺, which is present in almost all Caucasians and about 70% of black

Table 8.13 Drugs causing haemolysis in glucose-6-phosphate deficiency**Analgesics, such as:**

Aspirin
Phenacetin (withdrawn in the UK)

Antimalarials, such as:

Primaquine
Pyrimethamine
Quinine
Chloroquine
Pamaquin

Antibacterials, such as:

Most sulphonamides
Nitrofurantoin
Chloramphenicol
Quinolones

Miscellaneous drugs, such as:

Dapsone
Vitamin K
Probenecid
Quinidine
Dimercaprol
Phenylhydrazine
Methylene blue

Africans, and type A⁺, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African, or A⁺ type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock the Hb level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes

- Acute drug-induced haemolysis (Table 8.13) – usually dose-related
- Favism (ingestion of fava beans)
- Chronic haemolytic anaemia
- Neonatal jaundice
- Infections and acute illnesses will also precipitate haemolysis in patients with G6PD deficiency.

Mothballs containing naphthalene can also cause haemolysis.

The clinical features are due to rapid intravascular haemolysis with symptoms of anaemia, jaundice and haemoglobinuria.

Investigations

- **Blood count** is normal between attacks.
- **During an attack** the blood film may show irregularly contracted cells, bite cells (cells with an indentation of the membrane), blister cells (cells in which the Hb appears to have become partially detached from the cell membrane; Fig. 8.26), Heinz bodies (best seen on films stained with methyl violet) and reticulocytosis.
- **Haemolysis** is evident (see p. 387).
- **G6PD deficiency** can be detected using several screening tests, such as demonstration of the decreased ability of G6PD-deficient cells to reduce dyes. The level of the enzyme may also be directly assayed. There are two diagnostic problems. Immediately after an attack

**Figure 8.26** 'Blister' cells (arrowed) in G6PD deficiency.

the screening tests may be normal (because the oldest red cells with least G6PD activity are destroyed selectively). The diagnosis of heterozygous females may be difficult because the enzyme level may range from very low to normal depending on lyonization. However, the risk of clinically significant haemolysis is minimal in patients with borderline G6PD activity.

Treatment

- Any offending drugs should be stopped.
- Underlying infection should be treated.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

Pyruvate kinase deficiency

This is the most common defect of red cell metabolism after G6PD deficiency; it affects thousands rather than millions of people. The site of the defect is shown in Figure 8.25. There is reduced production of ATP, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive.

Investigations

- **Anaemia** of variable severity is present (Hb 50–100 g/L). The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG, and this reduces the severity of symptoms due to anaemia.
- **Blood film** shows distorted ('prickle') cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5–20%).

Treatment

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

Pyrimidine 5' nucleotidase deficiency

This autosomal disorder produces a haemolytic anaemia with basophilic stippling of the red cells. The enzyme degrades pyrimidine nucleotides to cytidine and uridine (pentose phosphate shunt), which in turn leads to the degradation of RNA in the reticulocytes. Lack of the enzyme results in accumulation of partially degraded RNA, which shows as basophilic stippling in mature red cells. The enzyme is also inhibited by lead (see p. 922) and thus basophilic stippling is seen in lead poisoning. The hereditary form can be diagnosed by measuring the enzyme in erythrocytes. A screening test using the ultraviolet absorption spectrum of red cells is available.

ACQUIRED HAEMOLYTIC ANAEMIA

These anaemias may be divided into those due to immune, non-immune, or other causes (Table 8.8).

Causes of immune destruction of red cells

- Autoantibodies
- Drug-induced antibodies
- Alloantibodies.

Causes of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 401)
- Mechanical factors (e.g. prosthetic heart valves, or microangiopathic haemolytic anaemia; see p. 371)
- Secondary to systemic disease (e.g. renal and liver disease).

Miscellaneous causes

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and products of *Clostridium welchii*).
- Malaria frequently causes anaemia owing to a combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (see p. 406) results in a reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns result in denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.

- Some ingested chemicals (e.g. weedkillers such as sodium chlorate) can cause severe oxidative haemolysis leading to acute kidney injury.

Autoimmune haemolytic anaemias

Autoimmune haemolytic anaemias (AIHA) are acquired disorders resulting from increased red cell destruction due to red cell autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs') test, which detects the autoantibody on the surface of the patient's red cells (Fig. 8.27).

AIHA is divided into 'warm' and 'cold' types, depending on whether the antibody attaches better to the red cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Table 8.14. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement, which is detected as C3d.

Immune destruction of red cells

IgM or IgG red cell antibodies which fully activate the complement cascade cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 8.28). They are either completely phagocytosed in the spleen through an interaction with Fc receptors on macrophages, or they lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis as macrophages also have receptors for C3b.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies

Figure 8.27 Antiglobulin (Coombs') tests. The anti-human globulin forms bridges between the sensitized cells causing visible agglutination. The direct test detects patients' cells sensitized *in vivo*. The indirect test detects normal cells sensitized *in vitro*. HDN, haemolytic disease of newborn.

Table 8.14 Causes and major features of autoimmune haemolytic anaemias

	Warm	Cold
Temperature at which antibody attaches best to red cells	37°C	Lower than 37°C
Type of antibody	IgG	IgM
Direct Coombs' test	Strongly positive	Positive
Causes of primary conditions	Idiopathic	Idiopathic
Causes of secondary condition	Autoimmune rheumatic disorders, e.g. SLE Chronic lymphocytic leukaemia Lymphomas Hodgkin's lymphoma Carcinomas Drugs, many including methyldopa, penicillins, cephalosporins, NSAIDs, quinine, interferon	Infections, e.g. infectious mononucleosis, <i>Mycoplasma pneumoniae</i> , other viral infections (rare) Lymphomas Paroxysmal cold haemoglobinuria (IgG)

Figure 8.28 Extravascular haemolysis is due to interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen. **(a)** Spherocytosis results from partial phagocytosis. **(b)** Complete phagocytosis may occur and this is enhanced if there is complement as well as antibody on the cell surface. **(c)** Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surface.

which partially rather than fully activate complement cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface.

'Warm' autoimmune haemolytic anaemias

Clinical features

These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice but they often remit and relapse and may progress to an intermittent chronic pattern. The spleen is often palpable. Infections or folate deficiency may provoke a profound fall in the haemoglobin level. Autoimmune haemolytic anaemias are primary or secondary. A history of blood transfusions and

infections, exposure to drugs or vaccination and the general clinical condition make the secondary form likely. If there is a suspicion of a drug related anaemia then stopping the drug is the obvious measure. The clinical examination will reveal any lymphadenopathy or splenomegaly. The commonest underlying cause is a lymphoproliferative disorder (Table 8.14).

Investigations

- **Haemolytic anaemia** is evident (see p. 387).
- **Spherocytosis** is present as a result of red cell damage.
- **Direct antiglobulin test** is positive, with either IgG alone (67%), IgG and complement (20%) or complement alone (13%) being found on the surface of the red cells.
- **Autoantibodies** may have specificity for the Rh blood group system (e.g. for the e-antigen).

- **Autoimmune thrombocytopenia** and/or neutropenia may also be present (Evans' syndrome).
- **Abdominal CT scan** for the detection of splenomegaly or abdominal lymphoma.

Treatment and prognosis

Corticosteroids (e.g. prednisolone in doses of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both production of the red cell autoantibody and destruction of antibody-coated cells. Splenectomy is the most effective second-line therapy. Other immunosuppressive drugs, such as azathioprine and rituximab, may be effective in patients who fail to respond to steroids and splenectomy. Blood transfusion may be necessary if there is severe anaemia although compatibility testing is complicated by the presence of red cell autoantibodies.

'Cold' autoimmune haemolytic anaemias

Normally, low titres of IgM cold agglutinins reacting at 4°C are present in plasma and are harmless. At low temperatures, these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as *Mycoplasma*, cytomegalovirus, Epstein-Barr virus (EBV)), there is increased synthesis of polyclonal cold agglutinins producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease (CHAD)

This usually occurs in the elderly with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud's as a result of red cell autoagglutination.

Investigations

- **Red cells** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily seen on the peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 376).
- **Cold agglutinin test** (the titre is markedly elevated in CHAD to >1:512)
- **Direct antiglobulin test** is positive with complement (C3d) alone.
- **Monoclonal IgM antibodies** with specificity for the Ii blood group system, usually for the I antigen but occasionally for the i antigen.

Treatment

The underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents and splenectomy are usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult due to the cold agglutinin.

Paroxysmal cold haemoglobinuria (PCH)

This is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox.

Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated *in vitro* by incubating the patient's red cells and serum at 4°C and then warming the mixture to 37°C (Donath-Landsteiner test). Haemolysis is self-limiting but red cell transfusions may be necessary.

Drug-induced immune haemolytic anaemia

Drug-induced haemolytic anaemias are rare, although over 100 drugs have been reported to cause immune haemolytic anaemia. The interaction between a drug and red cell membrane may produce three types of antibodies:

- **Antibodies to the drug** only, e.g. quinidine, rifampicin. Immune complexes attach to red cells, and may cause acute and severe intravascular haemolysis, sometimes associated with kidney injury. The haemolysis usually resolves quickly once the drug is withdrawn.
- **Antibodies to the cell membrane** only, e.g. methyldopa, fludarabine. There is extravascular haemolysis and the clinical course tends to be more protracted.
- **Antibodies to part-drug, part-cell membrane**, e.g. penicillin. This develops only in patients receiving large doses of penicillin. The haemolysis typically develops over 7–10 days, and recovery is gradual after drug withdrawal.

Confirmation of the diagnosis of drug-induced immune haemolytic anaemia requires:

- A temporal association between administration of a drug and haemolytic anaemia
- Recovery after withdrawal of the drug
- The direct antiglobulin test should be positive
- Drug-dependent red cell antibodies are detectable in the first and third mechanisms described above. In the second, the antibodies are not drug-dependent and are indistinguishable from autoantibodies.

Alloimmune haemolytic anaemia

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, haemolytic transfusion reactions (see p. 400) and after allogeneic bone marrow, renal, liver, cardiac or intestinal transplantation when donor lymphocytes transferred in the allograft ('passenger lymphocytes') may produce red cell antibodies against the recipient and cause haemolytic anaemia.

Haemolytic disease of the newborn (HDN)

HDN is due to fetomaternal incompatibility for red cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.

HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see below). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 407).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times, for example after a miscarriage, ectopic pregnancy or blood transfusion, or due to episodes during pregnancy which cause transplacental bleeding such as amniocentesis, chorionic villus sampling and threatened miscarriage.

Clinical features

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks' gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, where the unconjugated (lipid-soluble) bilirubin exceeds 250 µmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis and spasticity. In mild cases, it may present as deafness.

Investigations

Routine antenatal serology

All mothers should have their ABO and RhD groups determined and tested for atypical antibodies after attending the antenatal booking clinic. These tests should be repeated at 28 weeks' gestation.

If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

Antenatal assessment and treatment

If a clinically significant antibody capable of causing HDN, e.g. anti-D, anti-c or anti-K, is detected, the father's phenotype provides useful information to predict the likelihood of the fetus carrying the relevant red cell antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA obtained by amniocentesis, chorionic villus sampling or fetal blood sampling. Soluble fetal DNA in maternal plasma can also be used for RhD typing, avoiding an invasive procedure.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routinely used. If the infant appears to have severe anaemia by non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly, and if necessary, an intravascular fetal transfusion of red cells is given.

At the birth of an affected infant

A sample of cord blood is obtained. This shows:

- Anaemia with a high reticulocyte count
- A positive direct antiglobulin test
- A raised serum bilirubin.

Postnatal management

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin. Biliverdin can be excreted by

the kidneys and this therefore reduces the chance of kernicterus. In more severely affected cases, exchange transfusion may be necessary to replace the infant's red cells and to remove bilirubin. Indications for exchange transfusion include:

- a cord Hb of <120 g/L (normal cord Hb is 136–196 g/L)
- a cord bilirubin of >60 µmol/L
- a later serum bilirubin of >300 µmol/L
- a rapidly rising serum bilirubin level.

Further exchange transfusions may be necessary to remove the unconjugated bilirubin.

The blood used for exchange transfusions should be ABO-compatible with the mother and infant, lack the antigen against which the maternal antibody is directed, be fresh (no more than 5 days from the day of collection) and be CMV-seronegative to prevent transmission of cytomegalovirus.

Prevention of RhD immunization in the mother

Anti-D should be given after delivery when all of the following are present:

- The mother is RhD negative
- The fetus is RhD positive
- There is no maternal anti-D detectable in the mother's serum; i.e. the mother is not already immunized.

The dose is 500 IU of IgG anti-D intramuscularly within 72 hours of delivery. The Kleihauer test is used to assess the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes HbA. HbF is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

It may be necessary to give prophylaxis to RhD-negative women at other times when sensitization may occur, e.g. after an ectopic pregnancy, threatened miscarriage or termination of pregnancy. The dose of anti-D is 250 IU before 20 weeks' gestation and 500 IU after 20 weeks. A Kleihauer test should be carried out after 20 weeks to determine if more anti-D is required.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1–2% became immunized by the time of delivery. Antenatal prophylaxis with anti-D has been shown to reduce the incidence of immunization during pregnancy, and its routine use has been implemented in the UK. It can be given as two doses of anti-D immunoglobulin of 500 IU or 1500 IU (one at 28 weeks' and one at 34 weeks' gestation) or as a single dose of 1500 IU either at 28 weeks' or between 28 and 30 weeks' gestation. Monoclonal anti-D could in principle replace polyclonal anti-D, which is collected from RhD-negative women immunized in pregnancy and deliberately immunized RhD-negative males, but it is likely to be some years before trials have been completed to confirm its safety and effectiveness.

Non-immune haemolytic anaemia

Paroxysmal nocturnal haemoglobinuria (PNH)

Paroxysmal nocturnal haemoglobinuria is a rare form of haemolytic anaemia which results from the clonal expression of haematopoietic stem cells that have mutations in the X-linked gene *PIG-A*. These mutations result in an impaired synthesis of glycosylphosphatidylinositol (GPI), which anchors many proteins to the cell surface such as decay

accelerating factor (DAF; CD55) and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55 and CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence the haemolytic action of complement continues.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically, only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency. Some patients present insidiously with signs of anaemia and recurrent abdominal pains.

Venous thrombotic episodes may occur at atypical sites and severe thromboses may occur, for example in hepatic (Budd–Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be due to complement-mediated activation of platelets deficient in CD55 and CD59. Another suggestion is that intravascular haemolysis, which releases haemoglobin in the plasma, lowers plasma nitric oxide, which causes the symptoms and venous thrombosis.

Investigations

- **Intravascular haemolysis** is evident (see p. 387).
- **Flow cytometric analysis** of red cells with anti-CD55 and anti-CD59.
- **Bone marrow** is sometimes hypoplastic (or even aplastic) despite haemolysis.

Treatment and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. However, treatment with eculizumab has revolutionized therapy. It is a recombinant humanized monoclonal antibody that prevents the cleavage of C5 (and therefore the formation of the membrane attack complex). It reduces intravascular haemolysis, haemoglobinuria, the need for transfusion and gives an improved quality of life. Vaccinate against *Neisseria meningitidis* 2 weeks before treatment.

Long-term anticoagulation may be necessary acutely for patients with recurrent thrombotic episodes. Its long-term value is unclear with the use of eculizumab. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin or bone marrow transplantation. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but it may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10–15 years.

Gene therapy will perhaps be possible in the future.

Mechanical haemolytic anaemia

Red cells may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation

of distorted red cells or 'fragments'. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system.

The causes of mechanical haemolytic anaemia include:

- Damaged artificial heart valves
- March haemoglobinuria, where there is damage to red cells in the feet associated with prolonged marching or running
- Microangiopathic haemolytic anaemia (MAHA), where fragmentation of red cells occurs in an abnormal microcirculation caused by malignant hypertension, eclampsia, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, vasculitis or disseminated intravascular coagulation.

MYELOPROLIFERATIVE DISORDERS

In these disorders, there is uncontrolled clonal proliferation of one or more of the cell lines in the bone marrow, namely erythroid, myeloid and megakaryocyte lines. Myeloproliferative disorders include polycythaemia vera (PV), essential thrombocythaemia (ET), myelofibrosis (all of which have a JAK-2 molecular lesion) and chronic myeloid leukaemia (CML) (a genetic BCR-ABL lesion). These disorders are grouped together as there can be transition from one disease to another; e.g. PV can lead to myelofibrosis. They may also transform to acute myeloblastic leukaemia. The non-leukaemic myeloproliferative disorders (PV, ET and myelofibrosis) will be discussed in this section. Chronic myeloid leukaemia is described on page 455.

Polycythaemia

Polycythaemia (or erythrocytosis) is defined as an increase in haemoglobin, PCV and red cell count. PCV is a more reliable indicator of polycythaemia than is Hb, which may be disproportionately low in iron deficiency. Polycythaemia can be divided into absolute erythrocytosis where there is a true increase in red cell volume, or relative erythrocytosis where the red cell volume is normal but there is a decrease in the plasma volume (Fig. 8.6).

Absolute erythrocytosis is due to primary polycythaemia (PV) or secondary polycythaemia. Secondary polycythaemia is due to either an appropriate increase in red cells in response to anoxia, or an inappropriate increase associated with tumours, such as a renal carcinoma. The causes of polycythaemia are given in Table 8.15.

Primary polycythaemia: polycythaemia vera (PV)

PV is a clonal stem cell disorder in which there is an alteration in the pluripotent progenitor cell leading to excessive proliferation of erythroid, myeloid and megakaryocytic progenitor cells. Over 95% of patients with PV have acquired mutations of the gene Janus Kinase 2 (JAK2). There is a V617F mutation which causes the substitution of phenylalanine for valine at position 617. JAK2 is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haematopoietic growth factors such as erythropoietin, in normal and neoplastic cells. The significance of the discovery is two-fold: first of immediate significance is the clinical utility of the

Table 8.15 Causes of polycythaemia

detection of JAK2 mutations for the diagnosis of PV and second is the prospect of the development of new treatments for the myeloproliferative disorders based on targeting JAK2 activity.

Clinical features

The onset is insidious. It usually presents in patients aged over 60 years with tiredness, depression, vertigo, tinnitus and visual disturbance. It should be noted that these symptoms are also common in the normal population over the age of 60 and consequently, PV is easily missed. These features, together with hypertension, angina, intermittent claudication and a tendency to bleed, are suggestive of PV.

Severe itching after a hot bath or when the patient is warm is common. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient is usually plethoric and has a deep dusky cyanosis. Injection of the conjunctivae is commonly seen. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis

Box 8.2 shows the revised WHO criteria for diagnosis in adults. The measurement of red cell and plasma volume is not necessary. There may be a raised serum uric acid, leucocyte alkaline phosphatase and a raised serum vitamin B₁₂ and vitamin B₁₂ binding protein (transcobalamin 1).

Course and management

Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. Treatment is aimed at keeping the PCV below 0.45 L/L and the platelet count below $400 \times 10^9/L$. There are three types of specific treatment:

- **Venesection.** The removal of 400–500 mL weekly will successfully relieve many of the symptoms of PV. Iron

Box 8.2 Polycythaemia vera (PV) – modified from revised WHO criteria for

Major criteria

- Haemoglobin >185 g/L in men, 165 g/L in women or other evidence of increased red cell volume
- Presence of JAK2 tyrosine kinase V617F or other functionally similar mutation such as JAK2 exon 12 mutation

Minor criteria

- Bone marrow biopsy, showing hypercellularity for age with trilineage growth (panmyelosis) with prominent erythroid, granulocytic and megakaryocytic proliferation
- Serum erythropoietin level below the reference range for normal
- Endogenous erythroid colony (EEC) formation *in vitro*^a
Diagnosis requires the presence of both major criteria and one minor criterion or the presence of the first major criterion together with two minor criteria.

^aEEC. This is not routinely available but colony formation in the absence of exogenous erythropoietin *in vitro* is 100% specific and sensitive in patients without previous treatment. (This research was originally published in: Tefferi A, Thiele J, Orazi A et al. Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007; 110:1092–1097. ©American Society of Hematology.)

deficiency limits erythropoiesis. Venesection is often used as the sole treatment and other therapy is reserved to control the thrombocytosis. The aim is to maintain a packed cell volume (PCV) of <0.45 L/L.

- **Chemotherapy.** Continuous or intermittent treatment with hydroxycarbamide (hydroxyurea) is used frequently because of the ease of controlling thrombocytosis and general safety in comparison to the alkylating agents such as busulfan, which carry an increased risk of acute leukaemia. Low-dose intermittent busulfan may be more convenient for elderly people, and this must be weighed against the potential risk of long-term complications.
- **Low-dose aspirin** 100 mg daily with the above treatments is used for patients with recurrent thrombotic episodes.
- **Anagrelide** inhibits megakaryocyte differentiation and is useful for thrombolysis.

General treatment

Radioactive ³²P is only given to patients over 70 years because of the increased risk of transformation to acute leukaemia. *Allopurinol* is given to block uric acid production. The pruritus is lessened by avoiding very hot baths. *H1-receptor antagonists* have largely proved unsuccessful in relieving distressing pruritus, but *H2-receptor antagonists* such as cimetidine are occasionally effective.

Surgery. Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk; 75% of patients have severe haemorrhage following surgery and 30% of these patients die. In an emergency, reduction of the haematocrit by venesection and appropriate fluid replacement must be carried out.

Prognosis

PV develops into myelofibrosis in 30% of cases and into acute myeloblastic leukaemia in 5% as part of the natural history of the disease.

Secondary polycythaemias

Many high-oxygen affinity haemoglobin mutants (HOAHM) have been described which lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital autosomal recessive disorder (Chuvash polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel–Lindau (VHL) gene, resulting in an increased production of erythropoietin.

The causes of secondary polycythaemias are shown in Table 8.15.

Serum erythropoietin (EPO) levels are normal or raised in secondary polycythaemia. Rarely the discovery of a high EPO level may be the clue to the presence of an EPO secreting tumour.

The *treatment* is that of the precipitating factor; e.g. renal or posterior fossa tumours need to be resected. The commonest cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin and this can produce polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Heavy smokers also often have respiratory disease.

Complications of secondary polycythaemia are similar to those seen in PV, including thrombosis, haemorrhage and cardiac failure, but the complications due to myeloproliferative disease such as progression to myelofibrosis or acute leukaemia do not develop. Venesection may be symptomatically helpful in the hypoxic patient, particularly if the PCV is above 0.55 L/L.

'Relative' or 'apparent' polycythaemia (Gaisböck's syndrome)

This condition was originally thought to be stress-induced. The red cell volume is normal, but as the result of a decreased plasma volume, there is a relative polycythaemia. 'Relative' polycythaemia is more common than PV and occurs in middle-aged men, particularly in smokers who are obese and hypertensive. The condition may present with cardiovascular problems such as myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesection the patient. Smoking should be stopped.

Essential thrombocythaemia

Essential thrombocythaemia (ET) is a myeloproliferative disorder closely related to PV. Patients have normal Hb levels and WBC but elevated platelet counts. At diagnosis the platelet count will usually be $>600 \times 10^9/L$, and may be as high as $2000 \times 10^9/L$ or rarely even higher. ET presents either symptomatically with thromboembolic or less commonly bleeding problems or incidentally (e.g. at a routine medical check).

The diagnosis of ET is not straightforward as there is no global gold standard test. The JAK2 mutation tests (see PV) are useful in that the gene is mutated in about half of all cases of ET, confirming a myeloproliferative disorder. For the remaining 50% of patient with a normal JAK2 gene, clinical assessment and observation over a period of time are required. As a generalization a person with a very high platelet count ($>1000 \times 10^9/L$) who is clinically normal with good health will most likely prove to have ET. In a patient with a lower platelet count, e.g. $600 \times 10^9/L$, and in poor health the diagnosis can be more difficult. Other disorders which may give rise to reactive high platelet counts include autoimmune rheumatic disorders and malignancy. Individuals who have been splenectomized (for any reason, including trauma) sometimes have high platelet counts.

Treatment

Treatment is with hydroxycarbamide (hydroxyurea), anagrelide or busulfan to control the platelet count to less than $400 \times 10^9/L$.

α -Interferon is also effective; it is administered by subcutaneous injection. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years.

Myelofibrosis

Myelofibrosis is a very debilitating chronic myeloproliferative neoplasm. It may be primary or develop late in the course of essential thrombocythaemia or polycythaemia vera. There is clonal proliferation of stem cells and myeloid metaplasia in the liver, spleen and other organs. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes which release fibroblast-stimulating factors such as platelet-derived growth factor.

Clinical features

The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a 'fullness' in the upper abdomen due to splenomegaly. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function. Other physical signs include anaemia, fever and massive splenomegaly (for other causes, see p. 406).

Investigations

- **Anaemia** with leucoerythroblastic features is present (see p. 413). Poikilocytes and red cells with characteristic tear-drop forms are seen. The WBC count may be over $100 \times 10^9/L$, and the differential WBC count may be very similar to that seen in chronic myeloid leukaemia (CML); later leucopenia may develop.
- **The platelet count** may be very high, but in later stages, thrombocytopenia occurs.
- **Bone marrow aspiration** is often unsuccessful and this gives a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.
- **The Philadelphia chromosome** is absent; this helps to distinguish myelofibrosis from most cases of CML.
- **JAK2 mutation** is present in approximately half of the cases.

Treatment

This consists of general supportive measures such as blood transfusion, folic acid, analgesics and allopurinol. If the spleen becomes very large and painful, and transfusion requirements are high, it may be advisable to perform splenectomy. Splenectomy may also result in relief of severe thrombocytopenia. Treatment for myelofibrosis is often difficult but an estimation of prognosis from a prognostic scoring system is a good basis to start planning a treatment strategy for the individual patient. This may range from observation alone in those with the best prognosis to drug treatment to allogeneic stem cell transplantation. A new and very promising development in the treatment of myelofibrosis is the targeted therapy with JAK inhibitors. Ruxolitinib is being used in trials and has shown benefit.

Table 8.16 World Health Organization MDS classification system

Disease	Marrow blasts (%)	Clinical presentation	Cytogenetic abnormalities (%)
Refractory anaemia (RA)	<5	Anaemia	25
RA with ring sideroblasts (RARS)	<5	Anaemia, ≥15% ringed sideroblasts in erythroid precursors	5–20
MDS with isolated del(5q) (5q-syndrome)	<5	Anaemia, normal platelets	100
Refractory cytopenia with multilineage dysplasia (RCMD)	<5	Bicytopenia or pancytopenia	50
Refractory anaemia with excess blasts-1	5–9	Cytopenias ± peripheral blood blasts (<5%)	30–50
Refractory anaemia with excess blasts-2	10–19	Cytopenias, peripheral blood blasts present	50–70
Myelodysplastic syndrome, unclassified	<5	Neutropenia or thrombocytopenia	50

MDS, myelodysplastic syndrome. From: Vardiman JW, Brunning RD, Arber DA et al. Introduction and overview of the classification of myeloid neoplasms. In: Swerdlow SH, Campo E, Harris NL et al. (eds). *WHO Classification of Tumors of Haemopoietic and Lymphoid Tissues*. Geneva: WHO; 2008, p. 18.

Prognosis

Patients may survive for ≥10 years; median survival is 3 years. Death may occur in 10–20% of cases from transformation to acute myeloblastic leukaemia. The most common causes of death are cardiovascular disease, infection and gastrointestinal bleeding.

Myelodysplasia

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders that are due to a defect in stem cells. They are characterized by increasing bone marrow failure with quantitative and qualitative abnormalities of all three myeloid cell lines (red cells, granulocyte/monocytes and platelets). The natural history of MDS is variable, but there is a high morbidity and mortality owing to bone marrow failure, and transformation into acute myeloblastic leukaemia occurs in about 30% of cases. WHO classification of the myelodysplastic syndrome is shown in Table 8.16.

Somatic point mutations are commonly seen. A poor survival is seen in those carrying mutations in *TP53*, *E2H2*, *ETV6*, *RUNX1* and *ASXL1*.

Clinical and laboratory features

MDS occurs mainly in the elderly, and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, monocytosis and thrombocytopenia, either alone or in combination. By contrast, in chronic myelomonocytic leukaemias (CMML), monocytes are $>1 \times 10^9/L$ and the WBC count may be $>100 \times 10^9/L$.

The bone marrow usually shows increased cellularity despite the pancytopenia. Dyserythropoiesis is present, and granulocyte precursors and megakaryocytes also have abnormal morphology. Ring sideroblasts are present in some types. Table 8.16 shows the classification and the clinical presentation.

Management

Patients with <5% blasts in the bone marrow are usually managed conservatively with red cell and platelet transfusions and antibiotics for infections, as they are needed. Haemopoietic growth factors (e.g. erythropoietin, G-CSF) may be useful in some patients.

Patients with >5% blasts have a less favourable prognosis, and a number of treatment options are available:

- **Supportive care** only is suitable for elderly patients with other medical problems.

- **'Gentle' chemotherapy** (low-dose or single-agent, e.g. azacytidine) may be useful in patients with high WBC counts.
- **Intensive chemotherapy** schedules used for acute myeloblastic leukaemia (see p. 454) may be tried in patients under the age of 60, but the remission rate is less, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration because of the defect in stem cells.
- **Lenalidomide** (a thalidomide analogue) has been proven to be remarkably successful in the treatment of early stage myelodysplasia with a chromosome 5q deletion (the 5q- syndrome). Avoid use in women of child-bearing age.
- **Bone marrow transplantation** offers the hope of cure in the small proportion of MDS patients who are under the age of 50 and who have an HLA-identical sibling or an unrelated HLA-matched donor.

THE SPLEEN

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- The red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- The white pulp, which has a structure similar to lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow the blood is 'skimmed', with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

Functions

Sequestration and phagocytosis. Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell-Jolly and Heinz bodies and sideroblastic granules have their particles removed by 'pitting' and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis. Pluripotential stem cells are present in the spleen and proliferate during severe

haematological stress, such as in haemolytic anaemia or thalassaemia major.

Immunological function. About 25% of the body's T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling. Up to one-third of the platelets are sequestered in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

Splenomegaly

Causes

A clinically palpable spleen can have many causes.

- Infection:
 - acute, e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis
 - chronic, e.g. tuberculosis and brucellosis
 - parasitic, e.g. malaria, kala-azar and schistosomiasis.
- Inflammation: rheumatoid arthritis, sarcoidosis, SLE.
- Haematological: haemolytic anaemia, haemoglobinopathies and the leukaemias, lymphomas and myeloproliferative disorders.
- Portal hypertension: liver disease.
- Miscellaneous: storage diseases, amyloid, primary and secondary neoplasias, tropical splenomegaly.

Massive splenomegaly. This is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher's disease.

Hypersplenism

This can result from splenomegaly due to any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty's syndrome) and lymphoma. Hypersplenism produces:

- pancytopenia
- haemolysis due to sequestration and destruction of red cells in the spleen
- increased plasma volume.

Treatment. This is often dependent on the underlying cause, but splenectomy is sometimes required for severe anaemia or thrombocytopenia.

Splenectomy

Splenectomy is performed mainly for:

- trauma
- immune thrombocytopenic purpura (see p. 419)
- haemolytic anaemias (see p. 386)
- hypersplenism.

Problems after splenectomy

An immediate problem is an increased platelet count (usually $600\text{--}1000 \times 10^9/\text{L}$) for 2–3 weeks. Thromboembolic phenomena may occur. In the longer term, there is an increased risk of overwhelming infections, particularly pneumococcal infections.

Prophylaxis against infection after splenectomy or splenic dysfunction (Box 8.3)

All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry

Box 8.3 Prophylaxis against infection after splenectomy or splenic dysfunction

Vaccinate 2–3 weeks before elective splenectomy.

- A 23-valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years
- Meningococcal group C conjugate vaccine
- Annual influenza vaccine
- *Haemophilus influenzae* type b (Hib) vaccine
- Long-term penicillin V 500 mg 12-hourly (if sensitive, use erythromycin)
- Meningococcal polysaccharide vaccine (ACWY) for travellers to Africa/Saudi Arabia, e.g. during Hajj and Umrah pilgrimages

Figure 8.29 Post-splenectomy film with Howell-Jolly bodies (arrowed), target cells and irregularly contracted cells.

a card or bracelet to alert health professionals to their risk of overwhelming infection.

Post-splenectomy haematological features

- **Thrombocytosis** persists in about 30% of cases.
- **The WBC count** is usually normal but there may be a mild lymphocytosis and monocytosis.
- **Abnormalities in red cell morphology** are the most prominent changes and include Howell-Jolly bodies (contain basophilic nuclear remnants), Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (Fig. 8.29). Pitted red cells can be counted.

Splenic atrophy

This is seen in sickle cell disease due to infarction. It is also seen in coeliac disease, in dermatitis herpetiformis, and occasionally in ulcerative colitis and essential thrombocythaemia. Post-splenectomy haematological features are seen.

BLOOD TRANSFUSION

The cells and proteins in the blood express antigens which are controlled by polymorphic genes; that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed *immune antibodies* and are usually IgG, in contrast to *naturally occurring antibodies*, such as ABO antibodies, which are made in

Phenotype	Genotype	Antigens	Antibodies	Frequency UK (%)
O	OO	None	Anti-A and anti-B	43
A	AA or AO	A	Anti-B	45
B	BB or BO	B	Anti-A	9
AB	AB	A and B	None	3

**Figure 8.30** Sugar chains in the ABO blood group system.

response to environmental antigens present in food and bacteria and which are usually IgM.

Blood groups

The blood groups are determined by antigens on the surface of red cells; more than 280 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g. Kell, Duffy, Kidd) may cause haemolytic transfusion reactions and/or haemolytic disease of the newborn (HDN).

ABO system

This blood group system involves naturally occurring IgM anti-A and anti-B antibodies which are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of a pair of allelic genes, *H* and *h*, and also three allelic genes, *A*, *B* and *O*, producing the genotypes and phenotypes shown in Table 8.17. The A, B and H antigens are very similar in structure; differences in the terminal sugars determine their specificity. The *H* gene codes for enzyme H, which attaches fucose to the basic glycoprotein backbone to form H substance, which is the precursor for A and B antigens (Fig. 8.30).

The *A* and *B* genes control specific enzymes responsible for the addition to H substance of *N*-acetylgalactosamine for Group A and *D*-galactose for Group B. The *O* gene is amorphic and does not transform H substance and therefore O is not antigenic. The A, B and H antigens are present on most body cells. These antigens are also found in soluble form in tissue fluids such as saliva and gastric juice in the 80% of the population who possess secretor genes.

Rh system

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD

positive red cells. The antibodies formed cause HDN and haemolytic transfusion reactions.

This system is coded by allelic genes, *C* and *c*, *E* and *e*, *D* and no *D*, which is signified as *d*; they are inherited as triplets on each chromosome 1, one from each pair of genes (i.e. *CDE/cde*). RhD-negative individuals have no D protein in the red cell membrane, which explains why it is so immunogenic when RhD-negative individuals are exposed to RhD antigen through transfusion or pregnancy. In Caucasians, the RhD-negative phenotype almost always results from a complete deletion of the RhD gene; in black Africans, it can also result from an inactive gene containing stop codons in the reading frame.

Procedure for blood transfusion

The safety of blood transfusion depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

Pre-transfusion compatibility testing

Blood grouping

The ABO and RhD groups of the patient are determined.

Antibody screening

The patient's serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient's serum or plasma is tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an

indirect antiglobulin test, see p. 398). About 10% of patients have a positive antibody screening result; in which case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

Selection of donor blood and crossmatching

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell antibodies (see below), for patients who are likely to be multitransfused and at high risk of developing antibodies, e.g. sickle cell disease, and many hospitals routinely provide Kell-negative blood for women of child-bearing age to minimize the risk of alloimmunization and subsequent HDN.

Crossmatching procedures

Patients without atypical red cell antibodies. The full crossmatch involves testing the patient's serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In many hospitals this serological crossmatch has been omitted as the negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. A greater risk is that of a transfusion error involving the collection of the patient sample or a mix-up of samples in the laboratory. Laboratories can use their information system to check the records of the patient and authorize the release of the donor units if a number of criteria are met (*computer or electronic crossmatching*), including:

- The system is automated for ABO and RhD grouping and antibody screening including positive sample identification and electronic transfer of results.
- The antibody screening procedure conforms to national recommendations.
- The patient's serum or plasma does not contain clinically significant red cell antibodies.
- The release of ABO incompatible blood must be prevented by conformation of laboratory computer software to the following requirements:
 - the issue of blood is not allowed if the patient has only been grouped once
 - the issue of blood is not allowed if the current group does not match the historical record
 - the system must not allow the reservation and release of units which are ABO incompatible with the patient.
- The laboratory must assure the validity of the ABO and RhD group of the donor blood either by written verification from the Blood Service supplying the donor units or confirmatory testing in the laboratory; the UK Blood Transfusion Services guarantee that the blood group information is correct.

Electronic issue can be extended to issue of previously unallocated blood at blood fridges remote from the main laboratory (*remote blood issue*). This is only possible using blood fridges electronically linked to the blood transfusion laboratory information system. The printing of compatibility labels for the blood and its collection are under electronic control using the same rules as electronic issue from the main laboratory. Issue of blood using this process reduces the time it takes to provide blood for patients needing it urgently, particularly at hospitals without a blood transfusion

laboratory because transport of blood from the central laboratory is not required. There are good examples of centralized transfusion services in cities such as Pittsburgh and Seattle in the USA, and this model is likely to be increasingly used in other developed countries including the UK.

Patients with atypical red cell antibodies. Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being the same ABO and RhD group as the patient. A full crossmatch should always be carried out.

Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed and Ortho Biovue systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

Blood ordering

Elective surgery

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching and the amount of blood that eventually becomes outdated. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as *'group and save'*; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary, i.e. in a few minutes, using the electronic crossmatch procedure. If a patient has atypical antibodies, compatible blood should always be reserved in advance; this may take several days if the patient has multiple or unusual antibodies.

Emergencies

There may be insufficient time for full pretransfusion testing. The options include:

- Blood required immediately – use of 2 units of O RhD-negative blood (*'emergency stock'*), to allow additional time for the laboratory to group the patient.
- Blood required in 10–15 min – use of blood of the same ABO and RhD groups as the patient (*'group compatible blood'*).
- Blood required in 45 min – most laboratories will be able to provide fully crossmatched blood within this time.

Complications of blood transfusion (Table 8.18)

In the USA, it has been mandatory to report transfusion-associated deaths to the Food and Drug Administration since 1975; such reports have provided useful data which have contributed to efforts to improve the safety of blood transfusion. Similar reporting schemes under the term *'haemovigilance'* have been set up in other countries, including the Serious Hazards of Transfusion (SHOT) scheme, which produced its first report in the UK in 1997. Figure 8.31 shows the reports to SHOT up to 2009, indicating that *'incorrect blood component transfused'* is the most frequent type of serious incident, and the second most frequent cause of mortality and serious morbidity after transfusion-related acute lung injury (TRALI). Errors at the time of collection of blood from the fridge and/or the administration of blood

(53%) were the commonest source of error in 2005, followed by laboratory errors (43%) and mistakes in the collection of blood samples for compatibility testing (5%). Death or serious morbidity can also be attributed to other complications of blood transfusion including transfusion-associated circulatory overload (TACO), transfusion-associated graft-versus-host disease (TA-GvHD) and bacterial infection of blood components.

Prevention of wrong blood transfusions

The serious consequences of such failures emphasize the need for meticulous checks at all stages in the procedure of blood transfusion. Written procedures and good training of staff are essential. Regular audit to ensure compliance with these procedures is also required. New approaches are also being used including the use of barcode patient identification and new technology at the bedside. Handheld devices can be used to prompt staff through the key steps and check that

the barcode on the patient's wristband matches the barcode on the unit of blood (Fig. 8.32).

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many 'foreign' antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization also occurs during pregnancy – to fetal antigens inherited from the father and not shared by the mother (see p. 400).

Alloimmunization does not usually cause clinical problems with the first transfusion but these may occur with subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue or organ transplants.

Incompatibility

This may result in poor survival of transfused cells, such as red cells and platelets, and also in harmful effects of the antigen–antibody reaction.

1. Red cells

Haemolytic transfusion reactions

Immediate reaction. This is the most serious complication of blood transfusion and is usually due to ABO incompatibility. There is complement activation by the antigen–antibody reaction, usually caused by IgM antibodies, leading to rigors, lumbar pain, dyspnoea, hypotension, haemoglobinuria and renal failure. The initial symptoms may occur a few minutes after starting the transfusion. Activation of coagulation also occurs and bleeding due to disseminated intravascular coagulation (DIC) is a bad prognostic sign. Emergency treatment for shock (p. 885) is needed to maintain the blood pressure and renal function.

Diagnosis

This is confirmed by finding evidence of haemolysis (e.g. haemoglobinuria), and incompatibility between donor and recipient. All documentation should be checked to detect errors such as:

- Failure to check the identity of the patient when taking the sample for compatibility testing (i.e. sample from the wrong patient)

Table 8.18 Complications of blood transfusion	
Immunological	Non-immunological
Alloimmunization and incompatibility	Transmission of infection
<i>Red cells</i>	Viruses
Immediate haemolytic transfusion reactions	HAV, HBV, HCV
Delayed haemolytic transfusion reactions	HIV, HHV8
<i>Leucocytes and platelets</i>	CMV, EBV, HTLV-1, WNV
Non-haemolytic (febrile) transfusion reactions	Parasites
Post-transfusion purpura	Malaria, trypanosomiasis, toxoplasmosis
Poor survival of transfused platelets and granulocytes	Bacteria
Graft-versus-host disease	Prion – CJD
Lung injury (TRALI)	Circulatory failure due to volume overload
<i>Plasma proteins</i>	Iron overload due to multiple transfusions (see p. 391)
Urticarial and anaphylactic reactions	Massive transfusion of stored blood may cause bleeding reactions and electrolyte changes
	Physical damage due to freezing or heating
	Thrombophlebitis
	Air embolism

Figure 8.31 Overview of 6653 cases reported to the Serious Hazards of Transfusion (SHOT) scheme between 1996 and 2009. ATR, acute transfusion reaction; HSE, handling and storage errors; HTR, haemolytic transfusion reaction; I and U, inappropriate and unnecessary; IBCT, incorrect blood component transfused; PTP, post-transfusion purpura; TACO, transfusion-associated circulatory overload; TAD, transfusion-associated dyspnoea; TA-GvHD, transfusion-associated graft-vs-host disease; TRALI, transfusion-related acute lung injury; TTI, transfusion-transmitted infection. (From the Serious Hazards of Transfusion Steering Group, SHOT Annual Report 2010 Summary, with permission.)

Figure 8.32 Bedside checks. The traditional method of pre-transfusion bedside checking requires two nurses and checks of multiple items of written documentation. With barcode technology, a handheld computer reads a barcode on the patient wristband containing full patient details. The handheld computer checks that the patient details on the wristband barcode match those on the barcode (in the red box) on the compatibility label attached to the unit after pre-transfusion testing. This barcode also contains the unique number of the unit, and is matched with the barcode number of the unit (top left of the bag) to ensure that the blood bank has attached the right compatibility label. (This figure was originally published as the front cover of the September 2003 issue of *Transfusion* 43. Reproduced with permission from Wiley-Blackwell.)

- Mislabelling the blood sample with the wrong patient's name
- Simple labelling or handling errors in the laboratory
- Errors in the collection of blood, leading to delivery of the wrong blood to the ward/theatre
- Failure to perform proper identity checks before the blood is transfused (i.e. blood transfused to the wrong patient).

Investigations

To confirm where the error occurred, blood grouping should be carried out on:

- the patient's original sample (used for the compatibility testing)
- a new sample taken from the patient after the reaction
- the donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

Delayed reaction. This occurs in patients alloimmunized by previous transfusions or pregnancies. The antibody level is too low to be detected by pretransfusion compatibility testing, but a secondary immune response occurs after transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular as the antibodies are IgG, and the patient may develop anaemia and jaundice

about a week after the transfusion, although most of these episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The direct antiglobulin test is positive and detection of the antibody is usually straightforward.

2. Leucocytes and platelets

Non-haemolytic (febrile) transfusion reactions

Febrile reactions are a common complication of blood transfusion in patients who have previously been transfused or pregnant. The usual causes are the presence of leucocyte antibodies in an alloimmunized recipient acting against donor leucocytes in red cell concentrates leading to release of pyrogens, or the release of cytokines from donor leucocytes in platelet concentrates. Typical signs are flushing and tachycardia, fever ($>38^{\circ}\text{C}$), chills and rigors. Aspirin may be used to reduce the fever, although it should not be used in patients with thrombocytopenia. The routine introduction of leucocyte-depleted blood in the UK, to minimize the risk of transmission of variant Creutzfeldt-Jakob disease (vCJD) by blood transfusion (see below), has reduced the incidence of febrile reactions. Universal leucocyte-depletion of all blood components is common in European countries, but the proportion of blood components which are leucocyte-depleted is variable across the USA.

Potent leucocyte antibodies in the plasma of donors, who are usually multiparous women, may cause TRALI characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on the chest X-ray. Prompt respiratory support is essential; mechanical ventilation is frequently necessary. It usually resolves within 48–96 hours, but the mortality is 16% in the 257 cases of TRALI reported to SHOT, up to 2009. The avoidance of female plasma in the preparation of FFP and testing female platelet donors for leucocyte antibodies has been implemented in many developed countries to reduce the risk of TRALI.

Platelets

Post-transfusion purpura. See page 420.

3. Plasma proteins

Urticaria and anaphylaxis

Urticarial reactions are often attributed to plasma protein incompatibility, but in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administration of chlorphenamine 10 mg i.v. are usually sufficient treatment.

Anaphylactic reactions (see p. 69) occasionally occur; severe reactions are seen in patients lacking IgA who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped and *epinephrine* (adrenaline) 0.5 mg i.m. and *chlorphenamine* 10 mg i.v. should be given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive washed red cells, autologous blood or blood from IgA-deficient donors for patients with IgA deficiency.

Immunosuppression

Transfusions are known to have a favourable effect on the survival of subsequent renal allografts, due to transfusion-induced immunomodulation. The precise mechanism is unclear, but may be associated with the transfusion of allogeneic leucocytes. Other possible clinical effects caused

by transfusion-induced immunosuppression, such as an increase in postoperative infection and tumour recurrence, have been proposed, but remain unproven.

Non-immunological complications

Transmission of infection

Viral transmission: donor blood in the UK is currently tested for HBV, HCV, HIV-1 and HTLV-1. CMV-seronegative tested blood is given to immunosuppressed patients who are susceptible to acquiring CMV. Blood services continue a vigilant search for new infectious agents ('emerging' infections) which may be transmitted by blood transfusion, and for methods to prevent their transmission including donor screening, testing and pathogen inactivation. Donor questionnaires record recent travel to exclude possible risks of West Nile virus (WNV) and severe acute respiratory syndrome (SARS). WNV is the causal agent of meningoencephalitis and has been transmitted by transfusion and transplantation in the USA.

The risk of transmission of viral infections by blood transfusion varies from country to country depending on factors such as the underlying prevalence of transfusion-transmitted infections in the population and the measures taken to minimize the risk of transmission. Viral transmission via blood transfusion is still a major issue in the developing world. In the UK, the incidence of transmission of HIV by blood transfusion is extremely low – <1 in 5 million units transfused. Prevention is based on self-exclusion of donors in 'high-risk' groups and testing each donation for anti-HIV. The incidence of transmission of HBV is about 1 in 400 000 units transfused. The incidence of HCV is <1 in 30 million units transfused since the introduction of testing donor plasma for viral nucleic acid.

Measures for inactivating viruses in plasma such as coagulation factor concentrates or intravenous immunoglobulin include treatment with solvents and detergents.

Bacterial contamination of blood components is rare but it is one of the most frequent causes of death associated with transfusion. Some organisms such as *Yersinia enterocolitica* can proliferate in red cell concentrates stored at 4°C, but platelet concentrates stored at 22°C are a more frequent cause of this problem. Measures to avoid bacterial contamination include strict donor arm cleansing, diversion of the initial blood collection to samples for testing rather than into the collection bag, and bacterial detection systems for platelet concentrates, which have been implemented in most developed countries including the USA. It was implemented in England in 2011.

Transfusion-transmitted syphilis is very rare. Spirochaetes do not survive for >72 hours in blood stored at 4°C, and each donation is tested using the *Treponema pallidum* haemagglutination assay (TPHA).

In the UK, there continues to be concern about the risk of transmitting the prion protein causing vCJD (see p. 113) by transfusion: four transmissions of vCJD have occurred following a blood transfusion in the UK. A number of measures have been taken in the UK, including universal leucocyte-depletion of blood components (in 1999) because the prion protein was thought to be primarily associated with lymphocytes. Blood donors are excluded if they have had a blood transfusion since 1980. UK donor plasma is not used for the manufacture of blood products; imported plasma from the USA is used instead. For children under the age of 16 years, fresh frozen plasma (FFP) is sourced from plasma (from unremunerated donors) imported from the USA, on

the basis that exposure to bovine spongiform encephalitis (BSE) from food was eliminated by 1 January 1996. FFP for this group is treated with methylthioninium chloride (methylene blue) to inactivate viruses.

While stringent measures are being taken to minimize the risk of transfusion-transmitted infection, it may never be possible to guarantee that donor blood is absolutely 'safe'. The current approach to the safety of blood components and plasma in the UK and other developed countries is cautious, but it is not an absolute guarantee of safety. Clinicians should always carefully consider the patient's requirement for transfusion, and only transfuse if clinically appropriate (see below).

Circulatory failure due to volume overload – see management of acute heart failure, page 723.

Iron overload – see page 391.

Strategies for the avoidance of unnecessary transfusion

These include:

- Strict criteria for the use of blood components and blood products
- Stopping drug therapy (anticoagulants and antiplatelet drugs) that may potentiate bleeding in surgical patients
- The identification and treatment of anaemia prior to surgery
- The use of anti-fibrinolytic drugs, e.g. aprotinin and tranexamic acid in major surgery
- **Recombinant factor VIIa** is licensed to treat patients with haemophilia with inhibitors, and is being used 'off-license' to treat patients with severe bleeding, e.g. postoperative, trauma, intracerebral haemorrhage. However, there is little evidence of its safety and effectiveness for this latter indication.

Artificial haemoglobin solutions and other blood substitutes suitable for clinical use have not yet been developed. They generally have a short intravascular half-life, and a recent meta-analysis found a significant risk of mortality and myocardial infarction.

Autologous transfusion

An alternative to using blood from volunteer donors is to use the patient's own blood. There are three types of autologous transfusion:

- **Predeposit.** The patient donates 2–5 units of blood at approximately weekly intervals before elective surgery.
- **Preoperative haemodilution.** 1 or 2 units of blood are removed from the patient immediately before surgery and retransfused to replace operative losses.
- **Blood salvage.** Blood lost during or after surgery may be collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria, bowel contents and tumour cells.

The use of predeposit autologous transfusion was largely driven by concerns about transfusion-transmitted infection particularly in the USA, but its use has decreased in the USA and most countries. It has been abandoned in the UK except for those rare patients where it is not possible to identify compatible blood because of multiple antibodies. There is little evidence that this approach reduces blood requirements, and blood is perceived as being 'safe'. Blood salvage

is increasingly being used as a way of avoiding the use of donor blood. In developing countries, autologous blood and blood from relatives are commonly used because of a lack of donor blood.

Blood, blood components and blood products

Most blood collected from donors is processed as follows:

- **Blood components**, such as red cell and platelet concentrates, fresh frozen plasma (FFP) and cryoprecipitate are prepared from a single donation of blood by simple separation methods such as centrifugation and are transfused without further processing. Platelet concentrates are also prepared by plateletpheresis (see below).
- **Blood products**, such as coagulation factor concentrates, albumin and immunoglobulin solutions, are prepared by complex processes using the plasma from many donors as the starting material (UK donor plasma is not used, see above).

In most circumstances it is preferable to transfuse only the blood component or product required by the patient ('component therapy') rather than use whole blood. This is the most effective way of using donor blood, which is a scarce resource, and reduces the risk of complications from transfusion of unnecessary components of the blood.

Whole blood

A unit of whole blood consists of 450 mL \pm 10% of blood from a suitable donor plus 63 mL of anticoagulant, which is then leucocyte depleted. Blood stored at 4°C is given a 'shelf-life' of 5 weeks in the UK (6 weeks in some other countries), when at least 70% of the transfused red cells should survive normally. Whole blood is now rarely used for transfusion; donated blood is processed into red cell concentrates and other blood components.

Red cell concentrates

Virtually all the plasma is removed and is replaced by about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L, but the viscosity is low as there are no plasma proteins in the additive solution, and this allows fast administration if necessary.

Washed red cell concentrates

These are preparations of red cells suspended in saline, produced by cell separators to remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.

Platelet concentrates

These are prepared either from whole blood by centrifugation or by plateletpheresis of single donors using cell separators. They may be stored for up to 5 days at 22°C with agitation. They are used to treat bleeding in patients with severe thrombocytopenia, and prophylactically to prevent bleeding in patients with bone marrow failure.

Granulocyte concentrates

These are prepared from whole blood as 'buffy coats' or from single donors using cell separators and are used for patients with severe neutropenia with definite evidence of bacterial infection. The numbers of granulocytes collected may be increased by treating donors with G-CSF and steroids.

Fresh frozen plasma

FFP is prepared by freezing the plasma from 1 unit of blood to -30°C to maintain the concentration of coagulation factors. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies. It may be further treated by a pathogen-inactivation process, e.g. methylene blue or solvent detergent, to minimize the risk of disease transmission. For children, see [page 411](#).

Cryoprecipitate

This is obtained by allowing the frozen plasma from a single donation to thaw at 4–8°C and removing the supernatant. The volume is about 20 mL and it is stored at -30°C . It contains factor VIII: C, von Willebrand factor (VWF) and fibrinogen, and may be useful in DIC and other conditions where the fibrinogen level is very low. It is no longer used for the treatment of haemophilia A and von Willebrand's disease because of the greater risk of virus transmission compared with virus-inactivated coagulation factor concentrates. Fibrinogen concentrates are now available, but not yet approved for the treatment of patients with acquired disorders of haemostasis such as massive transfusion.

Factor VIII and IX concentrates

These are freeze-dried preparations of specific coagulation factors prepared from large pools of plasma. They are used for treating patients with haemophilia and von Willebrand's disease, where recombinant coagulation factor concentrates are unavailable. Recombinant coagulation factor concentrates, where they are available, are the treatment of choice for patients with inherited coagulation factor deficiencies (see [p. 421](#)).

Albumin

There are two preparations:

- **Human albumin solution 4.5%** contains 45 g/L albumin and 160 mmol/L sodium. It is available in 50, 100, 250 and 500 mL bottles.
- **Human albumin solution 20%** contains approximately 200 g/L albumin and 130 mmol/L sodium and is available in 50 and 100 mL bottles.

Human albumin solutions are generally considered to be inappropriate fluids for acute volume replacement or for the treatment of shock because they are no more effective in these situations than synthetic colloid solutions such as polygelatins (Gelofusine) or hydroxyethyl starch (Haemaccel). However, albumin solutions are indicated for treatment of acute severe hypoalbuminaemia and as the replacement fluid for plasma exchange. The 20% albumin solution is particularly useful for patients with nephrotic syndrome or liver disease who are fluid overloaded and resistant to diuretics. Albumin solutions should not be used to treat patients with malnutrition or chronic renal or liver disease with low serum albumin.

Normal immunoglobulin

This is prepared from normal plasma. It is used in patients with hypogammaglobulinaemia, to prevent infections, and in patients with, for example, immune thrombocytopenic purpura (see [p. 419](#)).

Specific immunoglobulins

These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B and anti-varicella zoster.

THE WHITE CELL

The five types of leucocytes found in peripheral blood are: neutrophils, eosinophils and basophils (which are all called granulocytes) and lymphocytes and monocytes (see also Ch. 3). The development of these cells is shown in Figure 8.1.

Neutrophils

The earliest morphologically identifiable precursors of neutrophils in the bone marrow are myeloblasts, which are large cells constituting up to 3.5% of the nucleated cells in the marrow. The nucleus is large and contains 2–5 nucleoli. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nucleoli but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus with 2–5 lobes, with predominantly secondary granules in the cytoplasm, which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short, only 6–8 hours. In response to stimuli (e.g. infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a 'shift to the left' on a blood film).

Function

The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by coating of particles with immunoglobulin and complement (opsonization) as neutrophils have Fc and C3b receptors (see p. 52). The material is ingested into vacuoles where it is subjected to enzymic destruction, which is either oxygen-dependent with the generation of hydrogen peroxide (myeloperoxidase) or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in polycythaemia and myelofibrosis and reduced in CML.

Neutrophil leucocytosis

A rise in the number of circulating neutrophils to $>10 \times 10^9/L$ occurs in bacterial infections or as a result of tissue damage. This may also be seen in pregnancy, during exercise and after corticosteroid administration (Table 8.19). With any tissue necrosis there is a release of various soluble factors, causing a leucocytosis. Interleukin 1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis accompanying a myocardial infarction are a good example of this and may be wrongly attributed to infection.

A *leukaemoid reaction* (an overproduction of white cells, with many immature cells) may occur in severe infections, tuberculosis, malignant infiltration of the bone marrow and occasionally after haemorrhage or haemolysis.

Table 8.19 Neutrophil leucocytosis

Bacterial infections
Tissue necrosis, e.g. myocardial infarction, trauma
Inflammation, e.g. gout, rheumatoid arthritis
Drugs, e.g. corticosteroids, lithium
Haematological:
Myeloproliferative disease
Leukaemoid reaction
Leucoerythroblastic anaemia
Physiological, e.g. pregnancy, exercise
Malignant disease, e.g. bronchial, breast, gastric
Metabolic, e.g. renal failure, acidosis
Congenital, e.g. leucocyte adhesion deficiency, hereditary neutrophilia

Table 8.20 Causes of neutropenia

Acquired
Viral infection
Severe bacterial infection, e.g. typhoid
Felt's syndrome
Immune neutropenia – autoimmune, autoimmune neonatal neutropenia
Pancytopenia from any cause, including drug-induced marrow aplasia (see p. 25)
Pure white cell aplasia
Inherited
Ethnic (neutropenia is common in black races)
Kostmann's syndrome (severe infantile agranulocytosis) due to mutation in elastase 2 (ELA2) gene
Cyclical (genetic mutation in ELA2 gene with neutropenia every 2–3 weeks)
Others, e.g. Schwachman–Diamond syndrome, dyskeratosis congenita, Chédiak–Higashi syndrome

In *leucoerythroblastic anaemia*, nucleated red cells and white cell precursors are found in the peripheral blood. Causes include marrow infiltration with metastatic carcinoma, myelofibrosis, osteopetrosis, myeloma, lymphoma, and occasionally severe haemolytic or megaloblastic anaemia.

Neutropenia and agranulocytosis

Neutropenia is defined as a circulatory neutrophil count below $1.5 \times 10^9/L$. A virtual absence of neutrophils is called agranulocytosis. The causes are given in Table 8.20. It should be noted that black patients may have somewhat lower neutrophil counts. Neutropenia caused by viruses is probably the most common type. Chemotherapy and radiotherapy predictably produce neutropenia; many other drugs have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

Clinical features

Infections may be frequent, often serious, and are more likely as the neutrophil count falls. An absolute neutrophil count of $<0.5 \times 10^9/L$ is regarded as 'severe' neutropenia and may be associated with life-threatening infections such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected.

Treatment

Antibiotics should be given as necessary to patients with acute severe neutropenia (see p. 449).

If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 373) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also used successfully in the treatment of chronic neutropenia.

Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

Eosinophils

Eosinophils are slightly larger than neutrophils and are characterized by a nucleus with usually two lobes and large cytoplasmic granules that stain deeply red. The eosinophil plays a part in allergic responses (see p. 52) and in the defence against infections with helminths and protozoa.

Eosinophilia is $>0.4 \times 10^9/L$ eosinophils in the peripheral blood. The causes of eosinophilia are listed in Table 8.21.

Basophils

The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large black granules. The granules contain histamine, heparin and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (see p. 68).

Basophils are usually few in number ($<1 \times 10^9/L$) but are significantly increased in myeloproliferative disorders.

Monocytes

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or

lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells and spend only a few hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis ($>0.8 \times 10^9/L$) may be seen in chronic bacterial infections such as tuberculosis or infective endocarditis, chronic neutropenia and patients with myelodysplasia, particularly chronic myelomonocytic leukaemia.

Lymphocytes

Lymphocytes form nearly half the circulating white cells. They descend from pluripotential stem cells (Fig. 8.1). Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 50).

Lymphocytosis (lymphocyte count $>5 \times 10^9/L$) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It also occurs in chronic lymphocytic leukaemia and in some lymphomas.

HAEMOSTASIS AND THROMBOSIS

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Haemostasis is the host defence mechanism that protects this integrity after injury to the vessel wall and tissue injury.

Haemostasis

Haemostasis is a complex process depending on interactions between the vessel wall, leucocytes, platelets, coagulation and fibrinolytic mechanisms. Haemostatic systems are normally quiescent but following tissue injury become rapidly activated. The formation of the haemostatic plug is shown in Figure 8.33.

Vessel wall

The vessel wall is lined by endothelium which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:

- Thrombomodulin and heparan sulphate expression
- Synthesis of prostacyclin (PGI_2) and nitric oxide (NO), which cause vasodilatation and inhibit platelet aggregation
- Production of plasminogen activator.

Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation and inhibition of fibrinolysis (Fig. 8.33).

Platelets

Platelet adhesion. When the vessel wall is damaged, the platelets escaping come into contact with and adhere to collagen and subendothelial bound von Willebrand factor. This adherence is mediated through glycoprotein Ib (GPIb). Glycoprotein IIb-IIIa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall platelets begin to undergo a shape change, from a disc to a sphere, spread along the subendothelium and release the contents of their cytoplasmic granules. These are the dense bodies (containing ADP and serotonin) and the

Platelet aggregation (Fig. 8.33b). As fibrinogen is a dimer it can form a direct bridge between platelets and so binds platelets into activated aggregates (platelet aggregation) and further platelet release of ADP occurs. A self-perpetuating

Figure 8.33 Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors. (a) Contact of platelets with collagen via the platelet receptor GP1b and factor VWF in plasma activates platelet prostaglandin synthesis which stimulates release of ADP from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A₂ (TXA₂) from platelets. (b) Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated leading to formation of fibrin. (c) Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells.

Figure 8.34 Prostaglandin synthesis.

cycle of events is set up leading to formation of a platelet plug at the site of the injury.

Coagulation. After platelet aggregation and release of ADP, the exposed platelet membrane phospholipids are available for the assembly of coagulation factor enzyme complexes (tenase and prothrombinase); this platelet phospholipid activity has been called platelet factor 3 (PF-3). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is platelet *prostaglandin synthesis*, which is induced by platelet activation and leads to the formation of TXA_2 in platelets (Fig. 8.34). Thromboxane (TXA_2) is a powerful vasoconstrictor and also lowers cyclic AMP levels and initiates the platelet release reaction. Prostacyclin (PGI_2) is synthesized in vascular endothelial cells and opposes the actions of TXA_2 . It produces vasodilatation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions leading to the conversion of soluble plasma fibrinogen to fibrin-based clot (Fig. 8.35). Roman numerals are used for most of the

Figure 8.35 Coagulation mechanism. The *in vivo* pathway begins with tissue factor–factor VIIa complex activating factor X and also factor IX. Factor XI is activated by thrombin. TF, tissue factor; TFPI, tissue factor pathway inhibitor.

factors, but I and II are referred to as fibrinogen and prothrombin respectively; III, IV and VI are redundant. The active forms are denoted by 'a'. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme precursors (factors XI, X, IX and thrombin) or cofactors (V and VIII), except for fibrinogen, which is polymerized to form fibrin.

Coagulation pathway

This enzymatic amplification system was traditionally divided into 'extrinsic' and 'intrinsic' pathways. This concept is useful for the interpretation of clinical laboratory tests such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) (see p. 417) but unrepresentative and an oversimplification of *in vivo* coagulation. Coagulation is initiated by tissue damage (Fig. 8.35):

- Tissue damage exposes tissue factor (TF) which binds to factor VII.
- The TF-factor VII complex directly converts factor X to active factor Xa and some factor IX to factor IXa.
- In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa.
- Following inhibition by TFPI the amount of factor Xa produced is insufficient to maintain coagulation. Further factor Xa, to allow haemostasis to progress to completion, can only be generated by the alternative factor IX/factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII, which dramatically increases the activity of factor IXa (generated by TF-factor VIIa) so further activation of factor X can proceed. Without the amplification and consolidating action of factor VIII/factor IX, bleeding will ensue as generation of factor Xa is insufficient to sustain haemostasis.
- Similarly thrombin activates factor V dramatically enhancing the conversion of prothrombin to thrombin by factor Xa.
- Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

Factor VIII consists of a molecule with coagulant activity (VIII: C) associated with von Willebrand factor. Factor VIII increases the activity of factor IXa by ~200 000 fold. VWF functions to prevent premature factor VIII: C breakdown and locate it to areas of vascular injury. VIII: C has a molecular weight of about 350 000.

Von Willebrand factor (VWF) is a glycoprotein with a molecular weight of about 200 000 which readily forms multimers in the circulation with molecular weights of up to 20×10^6 . It is synthesized by endothelial cells and megakaryocytes and stored in platelet granules as well as the endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active (see p. 422 and Fig. 8.39).

Physiological limitation of coagulation

Without a physiological system to limit blood coagulation dangerous thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

Antithrombin. Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of

Figure 8.36 Activation of protein C. PAI-1, plasminogen activator inhibitor 1.

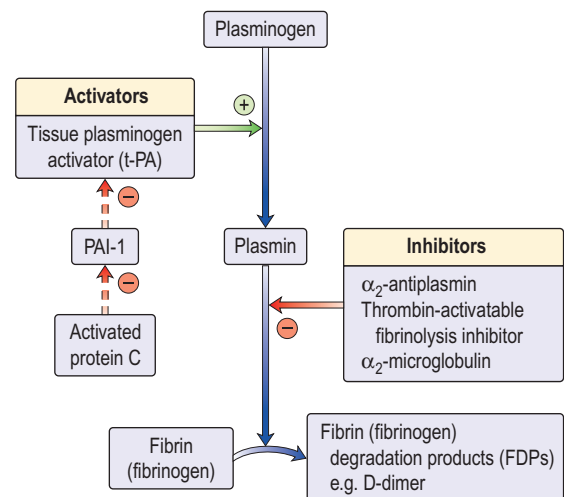

Figure 8.37 Fibrinolytic system. PA-1, plasminogen activator inhibitor-1.

coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

Activated protein C. This is generated from its vitamin K-dependent precursor, protein C, by thrombin; thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 8.36). Activated protein C inactivates factor V and factor VIII, reducing further thrombin generation.

Protein S. This is a cofactor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein but some 30–40% remains unbound and active (free protein S).

Other inhibitors. Other natural inhibitors of coagulation include α_2 -macroglobulin, α_1 -antitrypsin and α_2 -antiplasmin.

Fibrinolysis

Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen (Fig. 8.37). This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) are of minor physiological importance.

Plasmin is a serine protease, which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively

Figure 8.38 Fibrinolysis. (a) The conversion of plasminogen to plasmin by plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA. (b) Free plasmin in the blood is rapidly inactivated by α_2 -antiplasmin. Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasmin(ogen) and fibrin and between plasmin and α_2 -antiplasmin.

known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

The fibrinolytic system is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not (Fig. 8.38).

t-PA is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (Fig. 8.36). Inactivators of plasmin, such as α_2 -antiplasmin (Fig. 8.38) and thrombin-activatable fibrinolysis inhibitor (TAFI), also contribute to the regulation of fibrinolysis.

Investigation of bleeding disorders

Although the precise diagnosis of a bleeding disorder will depend on laboratory tests, much information is obtained from the history and physical examination:

- **Is there a generalized haemostatic defect?**
Supportive evidence for this includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.
- **Is the defect inherited or acquired?** A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, while mild inherited defects may only come to attention later in life, for example with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some defects are revealed by routine coagulation screens which are performed before surgical procedures.
- **Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

Vascular/platelet bleeding is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. Purpura includes both petechiae, which are small skin haemorrhages varying from pinpoint size to a few millimetres in diameter and which do not blanch on pressure, and ecchymoses, which are larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes especially the nose and mouth.

Coagulation disorders are typically associated with bleeding after injury or surgery, and in more severe forms, haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

Laboratory investigations

- **Blood count and film** show the number and morphology of platelets and any blood disorder such as leukaemia or lymphoma. The normal range for the platelet count is $150\text{--}400 \times 10^9/\text{L}$.
- **Coagulation tests** are performed using blood collected into citrate, which neutralizes calcium ions and prevents clotting.

The prothrombin time (PT) (also see p. 428) is measured by adding tissue factor (thromboplastin) and calcium to the patient's plasma. The normal PT is 12–16 s and when used to measure oral anticoagulants is expressed as the international normalized ratio, INR (see p. 369). The PT measures VII, X, V, prothrombin and fibrinogen (classic 'extrinsic' pathway) and is prolonged with abnormalities of these factors. It may also be abnormal in liver disease, or if the patient is on warfarin.

The activated partial thromboplastin time (APTT) is also sometimes known as the PTT with kaolin (PTTK). It is performed by adding a surface activator (such as kaolin, micronized silica or ellagic acid), phospholipid (to mimic platelet membrane) and calcium to the patient's plasma. The normal APTT is 26–37 s and depends on the exact methodology. The APTT measures XII, XI, IX, VIII, X, V, prothrombin and fibrinogen (classic 'intrinsic' pathway) and is prolonged with deficiencies of one or more of these factors. It is not dependent on factor VII.

The thrombin time (TT) is performed by adding thrombin to the patient's plasma. The normal TT is 12–14 s, and it is prolonged with fibrinogen deficiency, qualitative defects of fibrinogen (dysfibrinogenaemia) or inhibitors such as heparin or FDPs.

Correction tests can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT due to coagulation factor deficiencies can be corrected by addition of normal plasma to the patient's plasma. Failure to correct after addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.

Factor assays are used to confirm coagulation defects, especially where a single inherited disorder is suspected.

Special tests of coagulation will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation and platelet granule contents.

Bleeding time measures platelet plug formation *in vivo*. A sphygmomanometer cuff is inflated to 40 mmHg and 1 mm deep, 1 cm long incisions in the forearm are made with a template. Wounds are blotted every 30 s and the time taken for bleeding to stop recorded (normally 3–10 min). Prolonged bleeding times are found in patients with platelet function defects, and there is a progressive prolongation with platelet counts less than $100 \times 10^9/\text{L}$ – hence the bleeding time should

not be performed at low platelet counts. Nowadays it is rarely done as it can scar and is painful.

Vascular disorders

The vascular disorders (Table 8.22) are characterized by easy bruising and bleeding into the skin. Bleeding from mucous membranes sometimes occurs but the bleeding is rarely severe. Laboratory investigations including the bleeding time are normal. The vascular disorders include the following.

Hereditary haemorrhagic telangiectasia is a rare disorder with autosomal dominant inheritance. Mutations occur in most cases in one of three genes, ENG, ALK1 or SMAD4, that encode components of the TGF- β signalling pathway that is involved in blood vessel development. Dilatation of capillaries and small arterioles produces characteristic small red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and gastrointestinal tract. Recurrent epistaxis and chronic gastrointestinal bleeding are the major problems which causes chronic iron deficiency anaemia. Vascular malformations also occur in pulmonary, hepatic cerebral and spinal vasculature.

Easy bruising syndrome is a common benign disorder occurring in otherwise healthy women. It is characterized by bruises on the arms, legs and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura due to steroids are both due to atrophy of the vascular supporting tissue.

Purpura due to infections is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic (see p. 127).

Henoch–Schönlein purpura (see p. 582) occurs mainly in children. It is a type III hypersensitivity (immune complex) reaction that is often preceded by an acute upper respiratory tract infection. Purpura is mainly seen on the legs and buttocks. Abdominal pain, arthritis, haematuria and glomerulonephritis also occur. Recovery is usually spontaneous, but some patients develop renal failure.

Episodes of inexplicable bleeding or bruising may represent abuse, either self-inflicted or caused by others. These

Platelet disorders

Bleeding due to thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts above $50 \times 10^9/L$, and severe spontaneous bleeding is unusual with platelet counts above $20 \times 10^9/L$ (Table 8.23).

Thrombocytopenia

This is caused by reduced platelet production in the bone marrow, excessive peripheral destruction of platelets or sequestration in an enlarged spleen (Table 8.24). The underlying cause may be revealed by history and examination but a bone marrow examination will show whether the numbers

of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of such conditions as paroxysmal nocturnal haemoglobinuria (PNH) or systemic lupus erythematosus (SLE).

In patients with thrombocytopenia due to failure of production, no specific treatment may be necessary but the underlying condition should be treated if possible. Where the platelet count is very low or the risk of bleeding is very high, then platelet transfusion is indicated.

Immune thrombocytopenic purpura (ITP)

Thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

ITP in children

This occurs most commonly in age group 2–6 years. ITP has an acute onset with mucocutaneous bleeding and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life-threatening hemorrhage is rare (~ 1%). Bone marrow examination is not usually performed unless treatment becomes necessary on clinical grounds.

ITP in adults

The presentation is usually less acute than in children. ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (Evans' syndrome). It is also seen in patients with chronic lymphocytic leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60–70% of patients, and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins IIb/IIIa and/or Ib.

Clinical features

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

Investigation

The only blood count abnormality is thrombocytopenia. Normal or increased numbers of megakaryocytes are found in the bone marrow (if examination is performed), which is otherwise normal. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis, which often depends on exclusion of other causes of excessive destruction of platelets.

Treatment

Children

Children do not usually require treatment. Where this is necessary on clinical grounds, corticosteroids, intravenous immunoglobulin (i.v. IgG) and anti-D are effective; i.v. IgG is effective in >80% of children and raises the count more rapidly than steroids. Treatment should be reserved for very serious bleeding or urgent surgery. Chronic ITP is rare and requires specialist management.

Adults

Patients with platelet counts $>30 \times 10^9/L$ generally require no treatment unless they are about to undergo a surgical

procedure. Patients with even lower platelet counts may not require treatment unless they have spontaneous bruising or bleeding.

First-line therapy consists of oral corticosteroids 1 mg/kg body weight. Approximately 66% will respond to prednisolone but relapse is common when the dose is reduced. Only 33% of patients can expect a long-term response and long-term remission is seen in only 10–20% of patients following stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for splenectomy.

Intravenous immunoglobulin (i.v. IgG) is effective. It raises platelet count in 75% and in 50% the platelet count will normalize. Responses are only transient (3–4 weeks) with little evidence of any lasting effect. However, it is very useful where a rapid rise in platelet count is desired, especially before surgery. There are also advocates for high-dose corticosteroids for additional therapy.

Second-line therapy involves splenectomy, to which the majority of patients respond – two-thirds will achieve a normal platelet count. Patients who do not have a complete response can still expect some improvement.

Third-line therapy. For those that fail splenectomy, a wide range of other therapies are available. These include high-dose corticosteroids, intravenous immunoglobulin, Rh0(D) immune globulin (anti-D), vinca alkaloids, danazol, immunosuppressive agents such as azathioprine, ciclosporin and dapsone, combination chemotherapy, mycophenolate mofetil. Major difficulties with many third-line therapies are modest response rates and slow onset of action. Consequently there is also interest in the use of specific immunomodulatory monoclonal antibodies such as rituximab, which yields a 60% response rate. Due to a relative lack of thrombopoietin in ITP, clinical trials of recombinant thrombopoietin have been undertaken. However, these were stopped because of thrombocytopenia arising due to neutralization of endogenous thrombopoietin by cross-reacting antibodies. Alternative drug development is now based on thrombopoietin receptor agonists that do not have any homology with native thrombopoietin. Two such drugs, eltrombopag and romiplostim, have been shown to significantly increase platelet count in ITP on a long-term basis and are approved drugs for refractory ITP. Platelet transfusions are reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

Other immune thrombocytopenias

Drugs cause immune thrombocytopenia by the same mechanisms as described for drug-induced immune haemolytic anaemia (see p. 400). The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

Heparin-induced thrombocytopenia. See page 427.

Neonatal alloimmune thrombocytopenia is due to fetal-maternal incompatibility for platelet-specific antigens, usually for HPA-1a (human platelet alloantigen), and is the platelet equivalent of haemolytic disease of the newborn (HDN). The mother is HPA-1a-negative and produces antibodies, which destroy the HPA-1a-positive fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a-negative volunteers or the mother herself. Severe bleeding such as intracranial haemorrhage may also occur in utero.

FURTHER READING

Imbach P, Crowther M. Thrombopoietin-receptor agonists for primary immune thrombocytopenia. *N Engl J Med* 2011; 365:734–741.

Antenatal treatment of the mother – usually with high-dose IgG and/or steroids – has been effective in preventing haemorrhage in severely affected cases.

Post-transfusion purpura (PTP) is rare, occurring 7–10 days after a transfusion of platelet containing blood components, usually red cells. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-1a in an HPA-1a-negative individual. PTP always occurs in patients previously immunized either by blood transfusion or by pregnancy – hence it is more common in women. The cause of the destruction of the patient's own platelets is not well understood, but they may be destroyed as 'bystanders' during the acute immune response to HPA-1a. PTP is self-limiting, but intravenous IgG or plasma exchange may be required in severe bleeding.

Thrombotic thrombocytopenic purpura (TTP)

(see p. 590)

TTP is a rare, but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and microangiopathic haemolytic anaemia with red cell fragmentation, often accompanied by acute kidney injury. The coagulation screen is usually normal but lactic dehydrogenase (LDH) levels are markedly raised as a result of haemolysis. TTP arises due to endothelial damage and microvascular thrombosis. This occurs due to a reduction in ADAMTS-13 (A Disintegrin-like and Metalloproteinase domain with Thrombospondin-type motifs), a protease which is normally responsible for regulating the size of VWF. ADAMTS-13 is needed to break down ultra large von Willebrand factor multimers (UL VWFMs) into smaller haemostatically active fragments that interact with platelets. Reduction in ADAMTS-13 results in the adhesion and aggregation of platelets to UL VWFMs and multiorgan microthrombi. In most sporadic cases there is a true deficiency of the ADAMTS-13, associated with antibodies to ADAMTS-13. In some congenital cases the deficiency is due to mutations in the ADAMTS-13 gene. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection and drug treatment, including the use of ticlopidine and clopidogrel. Such cases may have a variable ADAMTS-13 activity at presentation and may or may not have associated antibodies to ADAMTS-13.

Treatment

Treatment consists of plasma exchange as the mainstay of treatment. It provides a source of ADAMTS-13 and removes associated autoantibody in acute TTP. Cryoprecipitate and solvent-detergent FFP (fresh frozen plasma) both contain ADAMTS-13. Pulsed intravenous methylprednisolone is given acutely, as is increasingly rituximab as a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS-13. In secondary TTP cases, identifiable precipitating drugs should be stopped.

Platelet function disorders (Box 8.4)

These are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is normal or increased and the

Box 8.4 Inherited and acquired types of platelet dysfunction

Inherited

- **Glanzmann's thrombasthenia** – lack of platelet membrane glycoprotein IIb–IIIa complex resulting in defective fibrinogen binding and failure of platelet aggregation.
- **Bernard-Soulier syndrome** – lack of platelet membrane glycoprotein Ib–IX–V complex (the binding site for VWF), causing failure of platelet adhesion and moderate thrombocytopenia.
- **Storage pool disease** – lack of the storage pool of platelet dense bodies, causing poor platelet function.

Acquired

- Myeloproliferative disorders
- Renal and liver disease
- Paraproteinaemias
- Drug-induced, such as NSAIDs (aspirin) or other platelet inhibitory drugs.

bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations such as platelet aggregation studies and factor VIII: C and VWF assays, if von Willebrand's disease is suspected.

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible.

Bleeding in renal disease is multifactorial, although platelet dysfunction is a major component. The degree of the defect of haemostasis is broadly proportional to the plasma urea concentration – platelet function is impaired by urea, guanidinosuccinic acid and other phenolic metabolites that accumulate in chronic kidney disease. Dialysis partially corrects platelet function. The haematocrit should be increased to >0.30 and the use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

Thrombocytosis

The platelet count may rise above $400 \times 10^9/L$ as a result of:

- Splenectomy
- Malignant disease
- Inflammatory disorders such as rheumatoid arthritis and inflammatory bowel disease
- Major surgery and post haemorrhage
- Myeloproliferative disorders
- Iron deficiency.

Thus, thrombocytosis is part of the acute-phase reaction, although following splenectomy platelet numbers are also elevated because of the loss of a major site of platelet destruction.

Essential thrombocythaemia, a myeloproliferative disorder which is described on page 404, and other myeloproliferative conditions such as polycythaemia vera (PV), myelofibrosis and chronic myeloid leukaemia (CML) may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but a small dose of aspirin (75 mg) is also sometimes given. In myeloproliferative diseases the primary risk is thrombosis and specific action to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea),

is often taken. Paradoxically there is also a risk of abnormal bleeding if the platelet count is very high.

Inherited coagulation disorders

Inherited coagulation disorders are uncommon and usually involve deficiency of one factor only. Acquired coagulation disorders occur more frequently and almost always involve several coagulation factors (see p. 423).

In inherited coagulation disorders, deficiencies of all factors have been described. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand's disease.

Haemophilia A

This is due to a lack of factor VIII. VWF is normal in haemophilia (Fig. 8.39). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia, and a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

Although a large number of different genetic defects have been found in the factor VIII gene, including deletions, duplications, frameshift mutations and insertions, in approximately 50% of families with severe disease, a common gene inversion in intron 22 is causative. There is a high mutation rate, with one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical and laboratory features

The clinical features depend on the level of factor VIII. The normal level of factor VIII is 50–150 IU/dL.

- **Levels of less than 1 IU/dL (severe haemophilia)** are associated with frequent spontaneous bleeding from early life, typically into joints and muscles. Such recurrent bleeding into joints leads to joint deformity and crippling if adequate treatment is not given.
- **Levels of 1–5 IU/dL (moderate haemophilia)** are associated with severe bleeding following injury and occasional spontaneous bleeds.

Table 8.25 Blood changes in haemophilia A, von Willebrand's disease and vitamin K deficiency

	Haemophilia A	von Willebrand's disease	Vitamin K deficiency
Bleeding time	Normal	↑	Normal
PT	Normal	Normal	↑
APTT	↑+	↑±	↑
VIII: C	↓++	↓	Normal
VWF	Normal	↓	Normal

- **Levels above 5 IU/dL (mild haemophilia)** are associated usually with bleeding only after injury or surgery. Diagnosis in this group is often delayed until quite late in life.

With treatment, the most common causes of death in people with haemophilia are cancer and heart disease, as for the general population, although cerebral haemorrhage is much more frequent than in the general population. In recent years, HIV infection and liver disease (due to hepatitis C) have become a more common cause of death. These infections were acquired from blood transfusion by many patients that were treated with factor concentrates prior to 1986. Since 1986 such plasma-derived products are all virally inactivated with heat or chemicals.

The main laboratory features of haemophilia A are shown in Table 8.25. The abnormal findings are a prolonged APTT and a reduced level of factor VIII. The PT, bleeding time and VWF level are normal.

Treatment

Bleeding is treated by administration of factor VIII concentrate by intravenous infusion to achieve normalization of levels. For surgery levels should be kept to normal levels until healing has occurred.

Factor VIII has a half-life of 12 h and therefore must be administered at least twice daily to maintain the required therapeutic level. Continuous infusion is sometimes used to

cover surgery. Factor VIII concentrate is freeze-dried and available as a small volume infusion so facilitating treatment at home and allowing it to be administered by the patient immediately after bleeding has started, reducing the likelihood of chronic damage to joints and the need for inpatient care.

Factor VIII concentrate is available as plasma-derived and recombinant products. Recombinant products are the treatment of choice for people with haemophilia, but economic constraints often limit availability, particularly in developing countries.

To prevent recurrent bleeding into joints and subsequent joint damage, patients with severe haemophilia are given factor VIII infusions regularly three times per week. Such 'prophylaxis' treatment is usually started in early childhood (around 2 years of age).

Synthetic vasopressin (desmopressin – an analogue of vasopressin) – intravenous, subcutaneous or intranasal – produces a 3–5-fold rise in factor VIII and is very useful in patients with a baseline level of factor VIII >10 IU/dL. It avoids the complications associated with blood products and is useful for treating bleeding episodes in mild haemophilia and as prophylaxis before minor surgery. It is ineffective in severe haemophilia.

People with haemophilia should be registered at comprehensive care centres (CCC), which take responsibility for their full medical care, including social and psychological support.

Complications

Up to 30% of people with severe haemophilia will, during their lifetime, develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. The prevalence of inhibitors is, however, only 5–10% because inhibitory antibodies develop only rarely in moderate and mild haemophilia and often disappear spontaneously or with continued treatment.

Management of inhibitor patients is very difficult, as infused factor VIII is rapidly inactivated. Recombinant factor VIIa at very high 'pharmacological' levels can bypass factor IX/VIII activity and is an effective treatment in more than 80% of bleeding episodes in patients with high levels of inhibitor antibodies. Some prothrombin complex concentrates are also deliberately activated to produce factors, which also may 'bypass' the inhibitor and stop the bleeding.

The long-term aim of management is to eradicate the inhibitory antibody, particularly in those that have recently developed inhibitors. This is done using immune tolerance induction strategies, sometimes using additional immunosuppression and immunoabsorption.

Although a historical legacy of plasma-derived concentrates, the risk of viral transmission has been virtually eliminated (see p. 411).

Hepatitis A and B vaccination is offered routinely to all patients with haemophilia and von Willebrand's disease. The clinical consequences of haemophilia patients infected with HIV are similar to other HIV-infected patients (see p. 175), except that Kaposi's sarcoma does not occur. Similarly some hepatitis C infected patients progress to develop chronic liver disease and cirrhosis (see p. 323).

Carrier detection and antenatal diagnosis

Determination of carrier status in females begins with a family history and coagulation factor assays. Female carriers may have a low factor VIII level but the exact value is very variable, because of lyonization. Owing to this process early in

embryonic life (that is, random inactivation of one chromosome; see p. 36), some carriers have very low levels of factor VIII while others will have normal levels. Carrier detection is carried out using molecular genetic testing/mutation analysis. Antenatal diagnosis may be carried out by molecular analysis of chorionic villus biopsy at 11–12 weeks' gestation if selective termination is being considered or by third trimester amniocentesis if not.

Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to haemophilia A, but the incidence is only about 1 in 30 000 males. It has been identified as the type of haemophilia affecting the Russian Royal Family. The half-life of factor IX is longer at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. Desmopressin is ineffective. Gene therapy may be effective in managing severe haemophilia B.

Von Willebrand's disease (VWD)

In VWD, there is defective platelet function as well as factor VIII deficiency, and both are due to a deficiency or abnormality of VWF (Fig. 8.39). VWF plays a role in platelet adhesion to damaged subendothelium as well as stabilizing factor VIII in plasma (see p. 414).

The VWF gene is located on chromosome 12 and numerous mutations of the gene have been identified. VWD has been classified into three types:

- **Type 1** is partial quantitative deficiency of VWF and significant type 1 VWD is usually inherited as an autosomal dominant.
- **Type 2** is due to a qualitative abnormality of VWF, and it too is usually inherited as an autosomal dominant.
- **Type 3** is recessively inherited and patients have virtually complete deficiency of VWF. Their parents are often phenotypically normal.

Many subtypes of VWD are described, particularly type 2 variants, which reflect the specific qualitative changes in the VWF protein.

Clinical features

These are very variable. Type 1 and type 2 patients usually have relatively mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Type 3 patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in Table 8.25. These also include defective platelet aggregation with ristocetin.

Treatment

Treatment depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin where possible. Some plasma-derived factor VIII concentrates contain intact von Willebrand factor. These specific products are used to treat bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate is used as a source of VWF, but should be avoided if possible since it is not virus inactivated.

Acquired coagulation disorders

Vitamin K deficiency (see also p. 207)

Vitamin K is necessary for the γ -carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K may be due to:

- **inadequate stores**, as in haemorrhagic disease of the newborn and severe malnutrition (especially when combined with antibiotic treatment) (see p. 208)
- **malabsorption of vitamin K**, a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- **oral anticoagulant drugs**, which are vitamin K antagonists.

The PT and APTT are prolonged (Table 8.25) and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytonadione (vitamin K₁) 10 mg intravenously. Some correction of the PT is usual within 6 h but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K, and this may cause minor bleeding in the first week of life (*classical haemorrhagic disease of the newborn*). Vitamin K deficiency also causes *late haemorrhagic disease of the newborn*, which occurs 2–26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg i.m. vitamin K to all neonates (see p. 208). Concerns about the safety of this are unfounded.

Liver disease

Liver disease may result in a number of defects in haemostasis:

- **Vitamin K deficiency**. This occurs owing to intrahepatic or extrahepatic cholestasis.
- **Reduced synthesis**. Reduced synthesis of coagulation factors may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- **Thrombocytopenia**. This results from hypersplenism due to splenomegaly associated with portal hypertension or from folic acid deficiency.
- **Functional abnormalities**. Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.
- **Disseminated intravascular coagulation**. DIC (see below) occurs in acute liver failure.

Disseminated intravascular coagulation (DIC)

Causes of DIC are listed in Box 8.5. There is widespread generation of fibrin within blood vessels, owing to activation of coagulation by release of procoagulant material, and by diffuse endothelial damage or generalized platelet aggregation. Activation of leucocytes, particularly monocytes causing expression of tissue factor and the release of cytokines, may play a role in the development of DIC. There is consumption of platelets and coagulation factors and secondary activation

Box 8.5 Causes of DIC

- Malignant disease
- Septicaemia (e.g. Gram-negative including meningococcal)
- Haemolytic transfusion reactions
- Obstetric causes (e.g. abruptio placentae, amniotic fluid embolism, pre-eclampsia)
- Trauma, burns, surgery
- Other infections (e.g. falciparum malaria)
- Liver disease
- Snake bite

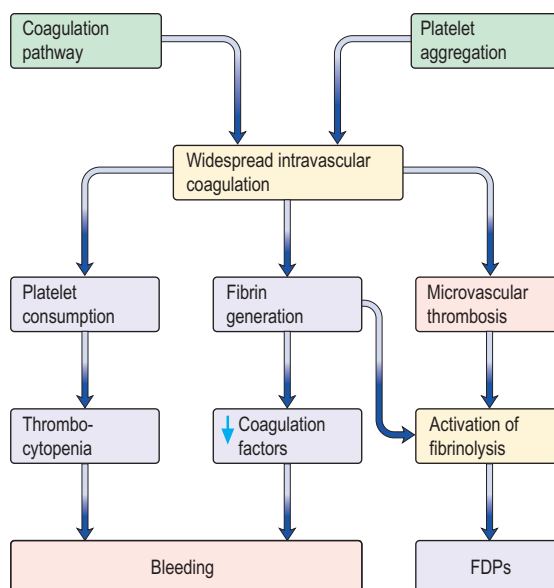

Figure 8.40 Disseminated intravascular coagulation. FDPs, fibrin degradation products.

of fibrinolysis leading to production of fibrin degradation products (FDPs), which contributes to the coagulation defect by inhibiting fibrin polymerization (Fig. 8.40). The consequences of these changes are a mixture of initial thrombosis followed by a bleeding tendency due to consumption of coagulation factors and fibrinolytic activation.

Clinical features

The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved, but the skin, brain and kidneys are most often affected.

Investigations

The diagnosis is often suggested by the underlying condition of the patient.

Severe cases with haemorrhage

- The PT, APTT and TT are usually very prolonged and the fibrinogen level markedly reduced.
- High levels of FDPs, including D-dimer, are found owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.

FURTHER READING

Tripodi A, Mannucci. The coagulopathy of chronic liver disease. *N Engl J Med* 2011; 365:147–156.

- There is severe thrombocytopenia.
- The blood film may show fragmented red blood cells.

Mild cases without bleeding

- Increased synthesis of coagulation factors and platelets
- Normal PT, APTT, TT and platelet counts
- FDPs are raised.

Treatment

The underlying condition is treated and this is often all that is necessary in patients who are not bleeding. Maintenance of blood volume and tissue perfusion is essential. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding. Inhibitors of fibrinolysis such as tranexamic acid should not be used in DIC as dangerous fibrin deposition may result. Activated protein C concentrates have been used in selected cases. In those cases with a dominant thrombotic component the use of heparin seems logical but there is little evidence to suggest any benefit.

Excessive fibrinolysis

Excessive fibrinolysis occurs during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.

Primary hyperfibrinolysis is very rare but activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to DIC with widespread bleeding. Laboratory investigations are also similar with a prolonged PT, APTT and TT, a low fibrinogen level, and increased FDPs, although fragmented red cells and thrombocytopenia are not seen, since disseminated coagulation is not present.

If the diagnosis is certain, fibrinolytic inhibitors such as epsilon-aminocaproic acid (EACA) or tranexamic acid can be given but evidence for efficacy is lacking.

Massive transfusion

Few platelets and reduced levels of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient's own blood volume within 24 hours, e.g. >10 units in an adult), the platelet count and PT and APTT should be checked at intervals.

Transfusion of platelet concentrates and FFP should be given if thrombocytopenia or defective coagulation are thought to be contributing to continued blood loss. Other problems of massive transfusion are described in Chapter 16.

Inhibitors of coagulation

Factor VIII autoantibodies arise occasionally in patients without haemophilia but with autoimmune disorders such as SLE, in elderly patients, with malignant disease and sometimes after childbirth. There can be severe bleeding. Immediate bleeding problems are managed as with bypassing factor concentrates (see p. 422). Longer-term therapy is to eliminate the autoantibody using immunosuppression, such as steroids, cyclophosphamide and, in severe cases, rituximab.

Lupus anticoagulant antibodies (see p. 538) are autoantibodies directed against phospholipids (antiphospholipid antibodies) and lead to prolongation of phospholipid

dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity.

Thrombosis

A thrombus is defined as a solid mass formed in the circulation from the constituents of the blood during life. Fragments of thrombi (emboli) may break off and block vessels downstream. Thromboembolic disease is much more common than abnormal bleeding; nearly half of adult deaths in England and Wales are due to coronary artery thrombosis, cerebral artery thrombosis or pulmonary embolism.

A thrombus results from a complex series of events involving coagulation factors, platelets, red blood cells and the vessel wall.

Arterial thrombosis

This usually occurs in association with atheroma, which tends to form at areas of turbulent blood flow such as the bifurcation of arteries. Platelets adhere to the damaged vascular endothelium and aggregate in response to ADP and TXA₂ to form a 'white thrombus'. The growth of the platelet thrombus is limited at its margins by PGI₂ and NO. Plaque rupture leads to the exposure of blood containing factor VIIa to tissue factor within the plaque, which may trigger blood coagulation and lead to thrombus formation. This results in complete occlusion of the vessel or embolization that produces distal obstruction. The risk factors for arterial thrombosis are related to the development of atherosclerosis (see p. 725).

Arterial thrombi may also form in the heart, as mural thrombi in the left ventricle after myocardial infarction, in the left atrium in mitral valve disease, or on the surfaces of prosthetic valves.

Venous thrombosis

Unlike arterial thrombosis, venous thrombosis often occurs in normal vessels. Major causes are stasis and hypercoagulability. The majority of venous thrombi occur in the deep veins of the leg, originating around the valves as 'red thrombi' consisting mainly of red cells and fibrin. The propagating thrombus is formed of fibrin and platelets and is particularly liable to embolize. Chronic venous obstruction following thrombosis in the deep veins of the leg frequently results in a permanently swollen limb and may lead to ulceration (post-phlebitic syndrome).

Risk factors for venous thrombosis are shown in Table 8.26. Venous thrombosis may occur with changes in blood cells such as polycythaemia and thrombocythaemia, and with coagulation abnormalities (thrombophilia; see below).

The clinical features and diagnosis of venous thrombosis are discussed on page 789.

Thrombophilia

Thrombophilia is a term describing inherited or acquired defects of haemostasis leading to a predisposition to venous or arterial thrombosis. It occurs in people with:

- Recurrent venous thrombosis
- Venous thrombosis for the first time under age 40 years
- An unusual venous thrombosis such as mesenteric or cerebral vein thrombosis
- Unexplained neonatal thrombosis
- Recurrent miscarriages
- Arterial thrombosis in the absence of arterial disease.

Table 8.26 Risk factors for venous thromboembolism**Patient factors**

Age
 BMI >30 kg/m²
 Varicose veins
 Continuous travel >3 h in preceding 4 weeks
 Immobility (bed rest ≥3 days)
 Pregnancy and puerperium
 Previous deep vein thrombosis or pulmonary embolism
 Thrombophilia
 Antithrombin deficiency
 Protein C or S deficiency
 Factor V Leiden
 Resistance to activated protein C (caused by factor V Leiden variant)
 Prothrombin gene variant
 Hyperhomocysteinaemia
 Antiphospholipid antibody/lupus anticoagulant
 Oestrogen therapy including HRT
 Dysfibrinogenaemia
 Plasminogen deficiency

Disease or surgical procedure

Trauma or surgery, especially of pelvis, hip or lower limb
 Malignancy
 Cardiac or respiratory failure
 Recent myocardial infarction or stroke
 Acute medical illness/severe infection
 Inflammatory bowel disease
 Behçet's disease
 Nephrotic syndrome
 Myeloproliferative disorders
 Paroxysmal nocturnal haemoglobinuria
 Paraproteinaemia
 Sickle cell anaemia
 Central venous catheter *in situ*

Coagulation abnormalities**Factor V Leiden**

Factor V Leiden differs from normal factor V by a single nucleotide substitution (Arg506Gln). This variation makes factor V less likely to be cleaved by activated protein C. As factor V is a cofactor for thrombin generation (Fig. 8.35) impaired inactivation by activated protein C (Fig. 8.36) results in a tendency to thrombosis. Factor V Leiden is found in 3–5% of healthy individuals in the western world and in about 20–30% of patients with venous thrombosis.

Factor V Leiden acts synergistically with other acquired thrombosis risk factors, for example in those taking oral contraceptive pills or when pregnant. Thrombosis risk rises 35-fold in those on a combined oral contraceptive pill although the absolute risk for thrombosis remains at significantly <0.5% per year for any single individual.

Prothrombin variant

A mutation in the 3' untranslated region of the prothrombin gene has been described (G20210A). This variant is associated with elevated levels of prothrombin and a 2–3-fold increase in the risk of venous thrombosis. There is an interaction with factor V Leiden and contraceptive pill use or pregnancy. The prevalence is 2% in Caucasian populations, 6% in unselected patients with thrombosis.

Antithrombin (AT) deficiency

This deficiency can be inherited as an autosomal dominant. Many variations have been described that lead to a conformational change in the protein. It can also be acquired following trauma, with major surgery and with the contraceptive pill. Low levels are also seen in severe proteinuria (e.g. the nephrotic syndrome). Recurrent thrombotic episodes occur starting at a young age in the inherited variety. Patients may

be relatively resistant to heparin as antithrombin is required for its action. Antithrombin concentrates are available.

Protein C and S deficiency

These autosomal dominant conditions result in an increased risk of venous thrombosis, often before the age of 40 years. Homozygous protein C or S deficiency causes neonatal purpura fulminans, which is fatal without immediate replacement therapy. Protein C concentrate and a recombinant activated protein C are available.

Antiphospholipid antibody

See page 538.

Homocysteine

When elevated, this amino acid is associated with both arterial thrombosis and venous thromboembolism. The mechanism of vascular damage is unclear. Folate, B₁₂ and B₆ supplementation are often helpful in reducing levels.

Investigations**Haemostatic screening test**

- **Full blood count** including platelet count
- **Coagulation screen** including a fibrinogen level. These tests will detect erythrocytosis, thrombocytosis, and dysfibrinogenaemia and the possible presence of a lupus anticoagulant.

Testing for specific causes of thrombophilia

- **Assays** for naturally occurring anticoagulants such as AT, protein C and protein S
- **Assay** for activated protein C resistance and molecular testing for factor V Leiden and the prothrombin variant
- **Screen for a coagulation factor** inhibitor including a lupus anticoagulant (and anticardiolipin antibodies) (see p. 538).

Prevention and treatment of arterial thrombosis

Attempts to prevent or reduce arterial thrombosis are directed mainly at minimizing factors predisposing to atherosclerosis. Treatment of established arterial thrombosis includes the use of antiplatelet drugs and thrombolytic therapy.

Antiplatelet drugs

Platelet activation at the site of vascular damage is crucial to the development of arterial thrombosis, and this can be altered by the following drugs (Table 8.27):

- **Aspirin** irreversibly inhibits the enzyme cyclo-oxygenase (COX), resulting in reduced platelet production of TXA₂ (Fig. 8.34). At the low doses used in cardiovascular disease prevention or treatment, there is selective inhibition of the isoform COX-1 found within platelets. This inhibition cannot be repaired and is effective for the life of the circulating platelet, which is about 1 week. In recent years, it has been suggested there may be significant individual variability in the response to aspirin, although there is no clear reason for this. The term 'aspirin resistance' has been loosely applied when the clinical effects of aspirin are less than expected. No large body of clinical trial data is specifically available to correlate clinical events and laboratory findings with respect to aspirin response and so it is difficult to determine if the breakthrough events experienced by patients treated with aspirin represent aspirin resistance

or are related to more mundane issues such as aspirin dose, drug interactions or drug non-compliance.

- **Dipyridamole** – which inhibits platelet phosphodiesterase, causing an increase in cyclic AMP with potentiation of the action of PGI_2 – has been used widely as an antithrombotic agent, but there is little evidence that it is effective.
- **Clopidogrel** – irreversibly blockades the ADP (P2Y_{12}) receptor on platelet cell membranes, so affecting the ADP-dependent activation of the glycoprotein IIb/IIIa complex. It is similar to ticlopidine but has fewer side-effects. Trials support its use in acute coronary syndromes (see p. 735).
- **Prasugrel**, a novel thienopyridine, is like clopidogrel and is licensed for use in acute coronary syndromes (see p. 735).
- **Glycoprotein IIb/IIIa receptor antagonists** block the receptor on the platelet for fibrinogen and von Willebrand factor (Fig. 8.41). Three classes have been described:

- murine-human chimeric antibodies (e.g. abciximab)
- synthetic peptides (e.g. eptifibatide)
- synthetic non-peptides (e.g. tirofiban).

They have been used as an adjunct in invasive coronary artery intervention and as primary medical therapy in coronary heart disease. Excessive bleeding has been a problem.

- **Epoprostenol** is a prostacyclin, which is used to inhibit platelet aggregation during renal dialysis (with or without heparin) and is also used in primary pulmonary hypertension.
- **Terutroban** is a thromboxane prostaglandin receptor antagonist which is being trialed in secondary prevention of cerebrovascular and cardiovascular disease as an alternative to aspirin.

The indications for and results of antiplatelet therapy are discussed in the appropriate sections (p. 735).

Thrombolytic therapy

Streptokinase

Streptokinase is a purified fraction of the filtrate obtained from cultures of haemolytic streptococci. It forms a complex with plasminogen, resulting in a conformational change, which activates other plasminogen molecules to form plasmin. Streptokinase is antigenic and the development of streptococcal antibodies precludes repeated use. Activation of plasminogen is indiscriminate so that both fibrin in clots and free fibrinogen are lysed, leading to low fibrinogen levels and the risk of haemorrhage.

Plasminogen activators

Tissue-type plasminogen activators (alteplase (t-PA), tenecteplase (TNK-tPA)) are produced by recombinant technology. Reteplase (r-PA) is also a recombinant plasminogen activator. They are not antigenic and do not give allergic reactions. They are relatively fibrin-specific, have relatively little systemic activity, and short half-lives (~5 min). The bleeding complications observed are similar in severity and frequency to those observed with streptokinase, suggesting that fibrin specificity does not confer protection against hemorrhage.

Indications

The use of thrombolytic therapy in myocardial infarction is discussed on page 739. The combination of aspirin with thrombolytic therapy produces better results than

Table 8.27 Drugs used in the treatment of thrombotic disorders

Antiplatelet

Aspirin
Thromboxane synthase, e.g. dipyridamole
GP IIb/IIIa inhibitors, e.g. abciximab, eptifibatide, tirofiban
ADP receptor antagonists/ P2Y_{12} inhibitors, e.g. clopidogrel, prasugrel, ticagrelor
Epoprostenol
Thromboxane prostaglandin receptor antagonists, e.g. terutroban

Thrombolytic

Streptokinase
Tissue-type plasminogen activator (t-PA or alteplase)
Reteplase (r-PA)
Tenecteplase (TNK-tPA)

Anticoagulant

Heparin:
Unfractionated (or standard)
Low molecular weight
Hirudin-like, e.g. lepirudin, bivalirudin
Fondaparinux
Warfarin
Bivalirudin
Xa inhibitors, e.g. apixaban, rivaroxaban, otamixaban, edoxaban, betrixaban
Direct thrombin inhibitors, e.g. dabigatran

Figure 8.41 The role of glycoprotein IIb/IIIa in platelet aggregation and the inhibition of platelet aggregation by inhibitors of glycoprotein IIb/IIIa receptors.

thrombolytic therapy alone. The extent of the benefit depends on how quickly treatment is given. They are also used in cerebral infarction (see p. 1102) and in massive pulmonary embolism where there is haemodynamic instability. The main risk of thrombolytic therapy is bleeding. Treatment should not be given to patients who have had recent bleeding, uncontrolled hypertension or a haemorrhagic stroke, or surgery or other invasive procedures within the previous 10 days.

Prevention and treatment of venous thromboembolism

Venous thromboembolism is a common problem after surgery, particularly in high-risk patients such as the elderly, those with malignant disease and those with a history of previous thrombosis (Table 8.28). The incidence is also high in patients confined to bed following trauma, myocardial infarction or other illnesses. The prevention and treatment of venous thrombosis includes the use of anticoagulants.

Table 8.28 Risk assessment for deep vein thrombosis and pulmonary embolism for hospital patients (NICE CG92)

Patients who are at risk of VTE	
Medical patients	Surgical patients and patients with trauma
If mobility significantly reduced for ≥ 3 days or If expected to have ongoing reduced mobility due to normal state plus any VTE risk factor	If total anaesthetic + surgical time >90 min or If surgery involves pelvis or lower limb and total anaesthetic + surgical time >60 min or If acute surgical admission with inflammatory or intra-abdominal condition or If expected to have significant reduction in mobility or If any VTE risk factor present
VTE risk factors ^a	
Active cancer or cancer treatment Age >60 years Critical care admission Dehydration Known thrombophilias Obesity (BMI >30 kg/m ²) One or more significant medical co-morbidities (e.g. heart disease, metabolic endocrine or respiratory pathologies, acute infectious diseases, inflammatory conditions) Personal history or 1st-degree relative with a history of VTE Use of HRT Use of oestrogen-containing contraceptive therapy Varicose veins with phlebitis	
Patients who are at risk of bleeding	
All patients who have any of the following: Active bleeding Acquired bleeding disorders (such as acute liver failure) Concurrent use of anticoagulants known to increase the risk of bleeding (such as warfarin with INR >2) Lumbar puncture/epidural/spinal anaesthesia within the previous 4 h or expected within the next 12 h Acute stroke Thrombocytopenia (platelets $<75 \times 10^9/L$) Uncontrolled systolic hypertension ($\geq 230/120$ mmHg) Untreated inherited bleeding disorders (such as haemophilia or von Willebrand's disease)	
^a For women who are pregnant or have given birth within the previous 6 weeks, see recommendations 1.6.4–1.6.6 in NICE guideline CG92.	

Anticoagulants

Heparin (standard or unfractionated)

Heparin is not a single substance but a mixture of polysaccharides. Commercially available unfractionated heparin consists of components with molecular weights varying from 5000 to 35000, with an average of about 13000. It was initially extracted from liver (hence its name) but it is now prepared from porcine gastric mucosa. Heparin acts immediately, binding to antithrombin. This induces a conformational change which increases the inhibitory activity of antithrombin (at least 5000-fold) towards activated serine protease coagulation factors (thrombin, XIIa, XIa, Xa, IXa and VIIa).

Low-molecular-weight heparins (LMW heparins)

These are produced by enzymatic or chemical degradation of standard heparin, producing fractions with molecular weights in the range of 2000–8000. Potentiation of thrombin inhibition (anti-IIa activity) requires a minimum length of the heparin molecule with an approximate molecular weight of 5400, whereas the inhibition of factor Xa requires only a smaller heparin molecule with a molecular weight of about 1700. LMW heparins have the following properties:

- Bioavailability is better than that of unfractionated heparin.
- They have greater activity against factor Xa than against factor IIa, suggesting that they may produce an equivalent anticoagulant effect to standard heparin but have a lower risk of bleeding, although this has not generally been confirmed. In addition, LMW heparins cause less inhibition of platelet function.
- They have a longer half-life than standard heparin and so can be given as a once-daily subcutaneous injection instead of every 8–12 h.
- They produce little effect on tests of overall coagulation, such as the APTT at doses recommended for prophylaxis. They are not fully neutralized by protamine.

LMW heparins are excreted renally and therefore dose reductions are required in those with renal impairment.

LMW heparins are widely used for antithrombotic prophylaxis, e.g. high-risk surgical patients and for the treatment of established thrombosis (see p. 747).

The main complication of all heparin treatment is bleeding. This is managed by stopping heparin. Very occasionally it is necessary to neutralize unfractionated heparin with protamine. Other complications include osteoporosis with prolonged therapy and thrombocytopenia.

Heparin-induced thrombocytopenia (HIT). HIT is an uncommon complication of heparin therapy and usually occurs 5–14 days after first heparin exposure. It is due to an immune response directed against heparin/platelet factor 4 complexes. All forms of heparin have been implicated but the problem occurs less often with LMW heparins.

HIT is paradoxically associated with severe thrombosis and when diagnosed all forms of heparin must be discontinued, including heparin flush. Unfortunately the diagnosis can be difficult to make because patients on heparin are often very sick and may be thrombocytopenic for many other reasons. Laboratory tests based on bioassay or immunoassay are available but are neither sensitive nor specific and management decisions often have to be made before results are available.

It is necessary to continue some form of anticoagulation in patients with HIT and the choice lies between the

heparinoid danaparoid and the direct thrombin inhibitor hirudin. The introduction of warfarin should be covered by one of these agents, as warfarin alone may exacerbate thrombosis as protein C levels fall.

Fondaparinux

This is a synthetic pentasaccharide, which inhibits activated factor X, similar to the LMW heparins. It is used in acute coronary syndrome (see p. 736). A long-acting version, idraparinux, which only needs to be given weekly is also available. Neither bind to platelet factor 4 and so have no capacity to cause HIT.

Direct thrombin inhibitors

A recombinant form of hirudin, lepirudin, is available. Hirudins bind directly to thrombin and are effectively irreversible inhibitors. They can be monitored by the use of the APTT and are excreted by the kidney, so must be used with caution in chronic kidney disease. *Lepirudin* is used for anticoagulation in patients with HIT.

Bivalirudin is a 20 amino acid synthetic analogue of hirudin. Compared with hirudin, it appears to cause less bleeding, is a reversible thrombin inhibitor (as it is broken down by thrombin) and has a shorter half-life. It is used in percutaneous coronary interventions.

Oral anticoagulants

These act by interfering with vitamin K metabolism. There are two types of oral anticoagulants, the coumarins and indandiones. The coumarin warfarin is most commonly used because it has a low incidence of side-effects other than bleeding.

The dosage is controlled by prothrombin tests (PT). Thromboplastin reagents for PT testing are derived from a variety of sources and give different PT results for the same plasma.

It is standard practice to compare each thromboplastin with an international reference preparation so that it can be assigned an international sensitivity index (ISI). The *international normalized ratio (INR)* is the ratio of the patient's PT to a normal control when using the international reference preparation. Therapeutic ranges using the INR for warfarin in various conditions are shown in Box 8.6.

Each laboratory can use a chart adapted to the ISI of their thromboplastin to convert the patient's PT to the INR. Suitably selected control plasmas can also be used to achieve the same objective. The use of this system means

that PT tests on a given plasma sample using different thromboplastins result in the same INR and that anticoagulant control is comparable in different hospitals across the world.

Contraindications to the use of oral anticoagulants are seldom absolute and include:

- Severe uncontrolled hypertension
- Non-thromboembolic strokes
- Peptic ulceration (unless cured by *Helicobacter pylori* eradication)
- Severe liver and renal disease
- Pre-existing haemostatic defects
- Non-compliance.

Warfarin should be avoided in pregnancy because they are teratogenic in the first trimester and may be associated with fetal haemorrhage later in pregnancy. When anticoagulation is considered essential in pregnancy, self-administered subcutaneous heparin should be used as an alternative, although this may not be as effective for women with prosthetic cardiac valves. Specialist advice should be sought.

Many drugs interact with warfarin (see Ch. 17). More frequent PT testing should accompany changes in medication, which should occur with the full knowledge of the anticoagulant clinic.

An increased anticoagulant effect due to warfarin is usually produced by one of the following mechanisms:

- Drugs causing a reduction in the metabolism of warfarin, including tricyclic antidepressants, cimetidine, sulphonamides, phenothiazines and amiodarone
- Drugs such as clofibrate and quinidine which increase the sensitivity of hepatic receptors to warfarin
- Drugs interfering with vitamin K absorption (such as broad-spectrum antibiotics and cholestyramine) which also potentiate the action of warfarin
- Displacement of warfarin from its binding site on serum albumin by drugs such as sulphonamides (this is not usually responsible for clinically relevant interactions)
- Drugs that inhibit platelet function (such as aspirin) which increase the risk of bleeding
- Alcohol excess, cardiac failure, liver or renal disease, hyperthyroidism and febrile illnesses which result in potentiation of the effect of warfarin.

A decreased anticoagulant effect due to warfarin This is usually produced by drugs that increase the clearance of warfarin by induction of hepatic enzymes that metabolize warfarin, such as rifampicin and barbiturates.

Anticoagulant related bleeding. Bleeding is the most serious side-effect of warfarin. Bleeding occurs in up to 4% of patients on oral anticoagulants per year, requires hospital admission in 2% and has a 0.25% morbidity associated with it. The benefit of anticoagulants must therefore be notably more than the risk of bleeding. Management of warfarin related bleeding (Emergency Box 8.1) is given dependent upon the INR and the degree of bleeding. Minor bleeding may be treated with cessation of warfarin alone, while serious bleeding will require additional use of vitamin K and factor concentrates.

New orally active anticoagulants

A large number of orally active direct thrombin (e.g. dabigatran) and Xa inhibitor drugs (e.g. rivaroxaban, apixaban) have been introduced for the treatment and prevention of venous and arterial thrombosis. Such drugs have a much broader therapeutic window than warfarin and offer the prospect of

Box 8.6 Indications for warfarin and target INR	
Target INR	
2.5	Pulmonary embolism, proximal and calf deep vein thrombosis, recurrence of venous thromboembolism when no longer on warfarin therapy, symptomatic inherited thrombophilia, atrial fibrillation, cardioversion, mural thrombus, cardiomyopathy
3.5	Recurrence of venous thromboembolism while on warfarin therapy, antiphospholipid syndrome, mechanical prosthetic heart valve, coronary artery graft thrombosis
<i>British Society for Haematology (2000).</i>	

Emergency Box 8.1

Management of warfarin-related bleeding and excessive oral anticoagulation

INR >3.0 <6.0 (target INR 2.5)	(1) Reduce warfarin dose or stop
INR >4.0 <6.0 (target INR 3.5)	(2) Restart warfarin when INR <5.0
INR >6.0 <8.0 no bleeding or minor bleeding	(1) Stop warfarin (2) Restart when INR <5.0
INR >8.0, no bleeding or minor bleeding	(1) Stop warfarin (2) Restart warfarin when INR <5.0 (3) If other risk factors for bleeding give 0.5–2.5 mg of vitamin K (oral)
Major bleeding	(1) Stop warfarin (2) Give prothrombin complex concentrate 50 U/kg (FFP 15 mL/kg if concentrate not available) (3) Give 5 mg of vitamin K (oral or i.v.)
If unexpected bleeding occurs investigate the possibility of a local anatomical cause.	
<i>Modified from British Society for Haematology (1998).</i>	

fixed drug dosing without the need to monitor coagulation. They do not however have specific antidotes. Dabigatran, apixiban and rivaroxaban are licensed for prevention of thrombosis in hip and knee replacement surgery as well as for the prevention of stroke in atrial fibrillation. Rivaroxaban is also licensed for the treatment of VTE. Large-scale studies in various aspects of thrombosis treatment and prevention are being undertaken using such drugs. These drugs, if clinical trial data is encouraging, will replace warfarin in a significant number of patients as they will be simpler to administer (no blood monitoring required) and as safe as, or safer than, warfarin with regard to bleeding.

Prophylaxis to prevent venous thromboembolism (VTE)

Risk factors for VTE are well defined. Most hospitalized patients have one or more of these risk factors and VTE is common in hospitalized patients. The risk of developing deep vein thrombosis (DVT) after hip replacement surgery has been estimated to be as high as 50% when thromboprophylaxis is not used. Approximately 10% of hospital deaths may be due to pulmonary embolism (PE) and more people die from hospital-acquired venous thrombosis than the combined deaths from road traffic accidents, AIDS and breast cancer. PE is the most common preventable cause of hospital death.

Appropriate thromboprophylaxis is highly effective and cost effective. Such prophylactic measures include early mobilization, elevation of the legs, compression stockings, intermittent compression devices and use of anticoagulant drugs, such as LMW heparins and thrombin inhibitors. All patients, medical and surgical, admitted to hospital should be risk assessed for thrombotic risk and given appropriate thromboprophylaxis. National guidelines are available to

guide appropriate management (NICE CG92). (See Table 8.28.)

Low-risk patients (Table 8.28) require no specific measures other than early mobilization.

High-risk patients based on risk assessment are most effectively managed using graduated compression stockings and LMW heparin subcutaneously daily.

The antithrombin agents dabigatran and rivaroxaban are routinely used after lower limb joint replacement surgery. They are as effective as LMW heparins and, as they are given orally, can be used for extended periods out of hospital.

Treatment of established venous thromboembolism

- **The aim** of anticoagulant treatment is to prevent further thrombosis and pulmonary embolization while resolution of venous thrombi occurs by natural fibrinolytic activity. Anticoagulation is started with heparin as it produces an immediate anticoagulant effect. Heparin should be administered for approximately 5 days, the time taken for simultaneously administered warfarin to produce an anticoagulant effect (INR 2.5).
- **LMW heparin** (e.g. tinzaparin 175 U/kg daily, dalteparin 200 U/kg daily, enoxaparin 1.5 mg/kg daily) is equally effective and as safe as unfractionated heparin in the immediate treatment of deep vein thrombosis and pulmonary embolism. This creates the opportunity for treatment of venous thromboembolism without admission to hospital, in compliant patients without co-existing risk factors for haemorrhage.
- **Length of anticoagulation.** This is recommended for at least 6 weeks after precipitated isolated calf vein thrombosis and at least 3 months after precipitated proximal DVT or PE in patients who have temporary risk factors. For patients with idiopathic VTE or permanent risk factors at least 3 months' anticoagulation is recommended and consideration should be given to indefinite anticoagulation.
- **Use of longer-term anticoagulation** in patients with previous thrombosis. It has been suggested that a lower INR might be safer and equally effective but the current view is that the target INR should be 2.0–3.0 where oral anticoagulation is used. Indefinite anticoagulation is considered appropriate for those with two or more episodes of VTE.
- **Outpatient anticoagulation** is best supervised in anticoagulant clinics. Patients are issued with national booklets for recording INR results and anticoagulant doses. Home monitoring is possible in well-motivated patients.

Inferior vena caval filters are an important tool to prevent PE in patients that have a contraindication to anticoagulation. Many are now retrievable allowing removal once a temporary contraindication to anticoagulation has passed. Long-term use of an IVC filter is associated with a risk of thrombosis at and below the site of the filter.

The role of thrombolytic therapy in the treatment of venous thrombosis is not established. It is used in patients with massive pulmonary embolism who are haemodynamically unstable and in patients with extensive deep venous thrombi.

Thrombolytic therapy should be followed by anticoagulation with heparin for a few days and then by oral anticoagulants to prevent rethrombosis.

INTRODUCTION

The term 'malignant disease' encompasses a wide range of illnesses, including common ones such as lung, breast and colorectal cancer (Table 9.1) as well as rare ones, like the acute leukaemias. Malignant disease is widely prevalent and, in the West, almost one-third of the population will develop cancer at some time during their life. It is second only to cardiovascular disease as the cause of death. Although the mortality of cancer is high, many advances have been made, both in terms of treatment and in understanding the biology of the disease at the molecular level.

THE BIOLOGY OF CANCER

Most human neoplasms are clonal in origin, i.e. they arise from a single population of precursor or cancer stem cells. This process is typically initiated by genetic aberrations within this precursor cell. Cancer is increasingly common the older we get and can be related to a time dependent accumulation of DNA damage that is not repaired by the normal mechanisms of genome maintenance, damage tolerance and checkpoint pathways. Malignant transformation may result from a gain in function as cellular proto-oncogenes become mutated (e.g. *ras*), amplified (e.g. *HER2*) or translocated (e.g. *BCR-ABL*). However, these mutations are insufficient to cause malignant transformation by themselves. Alternatively, there may be a loss of function of tumour suppressor genes such as P53 that normally suppress growth. Loss or gain of function may also involve alterations in the genes controlling the transcription of the oncogenes or tumour suppressor genes (p. 46). Over subsequent cell divisions, heterogeneity develops with the accumulation of further genetic abnormalities (Fig. 9.1).

The genes most commonly affected can be characterized as those controlling cell cycle checkpoints, DNA repair and

DNA damage recognition, apoptosis, differentiation, growth factor receptors and signalling pathways and tumour suppressor genes (Table 9.2). Recognition of critical genetic alterations has enabled extensive development of new targeted drugs such as imatinib that inhibits the growth signals of the abnormal tyrosine kinase *BCR/ABL*. Proliferation may continue at the expense of differentiation which, together with the failure of apoptosis, leads to tumour formation with the accumulation of morphologically abnormal cells varying in size, shape and cytoplasmic or nuclear maturity.

The hallmarks in developing cancer are shown in Figure 9.2.

Tumour immunology

Tumour cells are usually not recognized and killed by the immune system. There are two main reasons. The *first* is failure to express molecules such as HLA and co-stimulatory B7 molecules that are required for activation of cytotoxic, or 'killer', T lymphocytes. *Second*, tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression. Successful strategies for tumour vaccines that overcome these obstacles are developing in renal cancer and prostate cancer. The monoclonal antibody ipilimumab against the inhibitory cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) molecule that is expressed after T-cell activation, is used in melanoma (p. 479).

Angiogenesis

For many tumours, there is a progressive slowing of the rate of growth as the tumours become larger. This occurs for many reasons, but outgrowing the blood supply is paramount. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. The

Testis	95	

anti-VEGF-receptor monoclonal bevacizumab has had some success in colorectal and ovarian cancer.

Invasion and metastasis

Solid cancers spread by both local invasion and by distant metastasis through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion, which is mediated by active homotypic cell adhesion molecules (CAMs). Epithelial cadherin (E-cadherin) is expressed by many carcinomas and mutated in some such as familial gastric carcinoma (see p. 252).

Table 9.2 Common genetic abnormalities in cancer

Gene	Example
Control cell cycle checkpoints	Cyclin D1, p15, p16
DNA repair	FANCA, ATM
Apoptosis	Bcl2
Differentiation	PML/RARA
Growth factor receptors	EGF, VEGF, FGF, BCR/ABL, TGF- β , KIT, L-FLT3
Signalling pathways	RAS, BRAF, JAK2, NF1, PTCH
Hedgehog signalling pathway	See p. 26
Tumour suppressor genes	P53, Rb, WT1, VHL

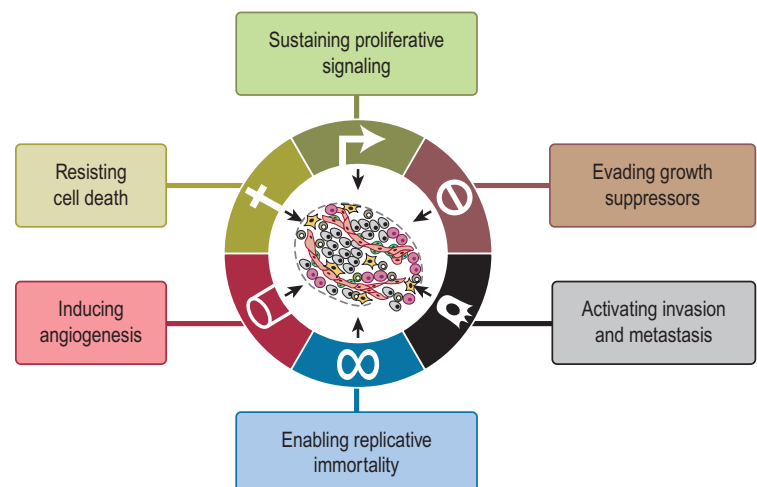

Figure 9.1 The adenoma–carcinoma progression sequence.

Figure 9.2 The hallmarks of cancer: the next generation. Six biological capabilities acquired during the multistep development of human tumours have been identified as shown in figure. Two others have been identified, viz reprogramming of energy metabolism and evading immune destruction. (From Hanagan D and Weinberg PA *The Hallmarks of cancer: the Next Generation*. Cell 2011;144:646–474 with permission.)

Invasion is also determined by the balance of activators to inhibitors of proteolysis. The matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are involved in tumour growth, invasion, metastasis and angiogenesis and are being targeted in new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance, but also because of specific interactions between receptors and cytokines found on stromal and tumour cells such as TNF, IL-6 and chemokines.

AETIOLOGY AND EPIDEMIOLOGY

For most patients, the cause of their cancer is unknown, probably representing a multifactorial interaction between individual genetic predispositions and environmental factors.

Genetic factors

Rather than occurring by somatic mutation in response to mutagens, germline mutations in the genes that predispose to the development of cancer may be inherited and therefore present in all tissues. Examples of such cancer syndromes are given in Table 9.3. Expression of the mutation and hence carcinogenesis, will depend upon the penetrance (due to the level of expression and the presence of other genetic events) of the gene and whether the mutated allele has a dominant or recessive effect. There is a small group of autosomal dominant inherited mutations such as RB (in retinoblastoma), and a small group of recessive mutations (Table 9.3). Carriers of the recessive mutations are at risk of developing cancer if the second allele becomes mutated, leading to 'loss of heterozygosity' within the tumour, although this is seldom sufficient as carcinogenesis is a multistep process.

Environmental factors

A wide range of environmental factors have been identified as being associated with the development of malignancy (Table 9.4) and may be amenable to preventative action such as smoking cessation, dietary modification and antiviral immunization (Box 9.1). Environmental factors interact with

genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence to those with a high incidence of breast or colon cancer acquire the cancer incidence of the country to which they have moved while northern European people exposed to strong UV radiation have the highest risk of developing melanoma.

Tobacco

The incidence of lung cancer in both men and women increased dramatically in the last 25 years worldwide, but is now falling in many developed countries. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified: cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, it is also associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on page 806.

Alcohol

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts, and it also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

Diet

Dietary factors have been attributed to account for one-third of cancer deaths, although it is often difficult to differentiate these from other epidemiological factors. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in

Box 9.1 Key messages for a healthy lifestyle for preventing cancer

- Stop smoking
- Moderate alcohol consumption
- Healthy weight
- Moderate exercise
- Healthy eating (fruit and vegetables, high fibre, low fat/salt/sugar)
- Limited sun exposure
- Minimize occupational risk
- Minimize radiation exposure
- Vaccination against hepatitis B and HPV

Table 9.4 Some causative factors associated with the development of cancer

Smoking	Mouth, pharynx, oesophagus, larynx, lung, bladder, lip
Alcohol	Mouth, pharynx, larynx, oesophagus, colorectal
Iatrogenic	
Alkylating agents	Bladder, bone marrow
Oestrogens	Endometrium, vagina, breast, cervix
Androgens	Prostate
Radiotherapy (e.g. mantle radiotherapy)	Carcinoma of breast and bronchus
Diet	
High-fat diet	Colorectal cancer
Environmental/occupation	
Vinyl chloride	Liver (angiosarcoma)
Polycyclic hydrocarbons	Skin, lung, bladder, myeloid leukaemia
Aromatic amines	Bladder
Asbestos	Lung, mesothelium
Ultraviolet light	Skin, lip
Radiation	e.g. leukaemia, thyroid cancer
Aflatoxin	Liver
Biological agents	
Hepatitis B virus	Liver (hepatocellular carcinoma)
Hepatitis C virus	Liver (hepatocellular carcinoma)
Human T-cell leukaemia virus	Leukaemia/lymphoma
Epstein–Barr virus	Burkitt's lymphoma
	Hodgkin's lymphoma
	Nasopharyngeal carcinoma
Human papillomavirus types 16, 18	Cervix
	Oral cancer (type 16)
<i>Schistosoma japonicum</i>	Bladder
<i>Helicobacter pylori</i>	Stomach

the Western, economically more developed countries. Many associations have been observed without a causative mechanism being identified between the incidence of cancer and the consumption of dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A and many others. Food and its role in the causation of gastrointestinal cancer is discussed in [Chapter 5](#) (see [p. 218](#)). Increasing levels of obesity in the developed world have been associated with increases in women of cancers associated with oestrogenic stimulation of the breast and endometrium.

Environmental/occupational

Ultraviolet light is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Arsenical contamination of water supplies has been linked to high incidence of lung and colon cancers in Southeast Asia particularly where bore holes are the main water source.

Occupational factors. In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps. The principal causes now are asbestos (lung and mesothelial cancer) and polycyclic hydrocarbons from fossil fuel combustion (skin, lung, bladder cancers). Organic chemicals, such as benzene, may cause the development of bone marrow conditions such as myelodysplastic syndrome or acute myeloid leukaemia.

Infectious agents

The geographical distribution of a rare malignancy suggests that it might be caused by, or associated with, an infective agent. Chronic persistent infection provides growth stimulation while many viruses contain transforming viral oncogenes.

T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the locally endemic retrovirus HTLV-1 (human T-cell leukaemia virus) and integration of the oncogene, *TAX*, into the cellular genome.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections and Burkitt's lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus. EBV is also linked with Hodgkin's lymphoma (see [p. 459](#)).

Patients with HIV infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi's sarcoma.

The incidence of cervical cancer had increased among younger women in association with sexually transmitted HPV (human papillomavirus) infection types 16 and 18, for which an effective vaccine is now available.

Bacterial infection with *Helicobacter pylori* predisposes to the development of gastric cancer and gastric lymphoma, while *Schistosoma japonicum* infection predisposes to the development of squamous cell carcinomas in the bladder.

Medications

Oestrogens have been implicated in the development of vaginal, endometrial and breast carcinoma. Certain cytotoxic drugs given, e.g. for Hodgkin's lymphoma (see later) are themselves associated with an increased incidence of secondary acute myelogenous leukaemia (AML), bladder and lung cancer. Androgens have been associated with both benign and malignant liver tumours.

Radiation

Accidental. The nuclear disasters of Hiroshima, Nagasaki and Chernobyl led to an increased incidence of leukaemia after 5–10 years in the exposed population as well as increased incidences of thyroid and breast cancer. Radiation workers are at an increased risk of malignancy due

Table 9.5 Radiation exposure from common diagnostic radiological procedures	
Procedure	mSv
CXR	0.02
IVU	3
CT chest	7
CT abdomen	8–10
Whole body CT	20
Percutaneous coronary intervention	15
Myocardial perfusion imaging	15.6

UK background radiation is 2.6 mSv per year. 1 mSv carries a lifetime cancer risk of 1 in 17 500 and 5 mSv a risk of 1 in 3500.
Modified from: Smith-Bindman R, Lipson J, Marcus R et al. *Archives of Internal Medicine* 2009; 169:2078–2086 and Fazel R, Krumholz HM, Wang Y et al. *New England Journal of Medicine* 2009; 361:849–857.

to occupational exposure unless precautions are taken to minimize this using personal and environmental shielding and to record and limit the amount of personal exposure.

Therapeutic. Long-term survivors following radiotherapy, e.g. for Hodgkin's lymphoma, have an increased incidence of cancer, particularly at the radiation field margins.

Diagnostic. Imaging procedures involving radiation exposure are associated with an increased risk of cancer. This risk is cumulative, dose dependent and time dependent, i.e. children are at higher risk than adults. The cancer risk of various common investigations is shown in Table 9.5. All doctors should strive to minimize diagnostic exposure to radiation where possible using alternative modalities such as ultrasound or MRI. Good documentation of radiation doses is required. This is particularly so in children and pregnant women.

Epidemiology

The incidence and mortality from cancer varies by tumour type and geographical region across the world.

Geographical distribution

The incidence of cancer across the world is dependent on the local environmental factors, the diet and the genetics of the population (see above) (Figs 9.3, 9.4). Age is also a factor as most cancers occur in those over the age of 65 who comprise 3.3% of the population in Africa compared with 15.2% in Europe. Reproductive patterns also influence breast cancer. Migrating individuals often take on the risks of the local environmental factors.

Other factors

Incidence and mortality are closely linked for cancers for which treatment has yet to make significant improvements such as lung, stomach and liver, while in countries with effective screening programmes, there is an increasing incidence and decreasing mortality for breast, cervix, bowel and prostate cancers.

THE CLINICAL PRESENTATION OF MALIGNANT DISEASE

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells and diagnosis only becomes likely once

Figure 9.3 The most common causes of death from cancer worldwide, excluding non-melanoma skin cancers (NMSC) 2002 estimates. (From: <http://info.cancerresearchuk.org/cancerstats/world/the-global-picture/>)

Figure 9.4 Percentage of all deaths due to cancer in the different regions of the world. (From: <http://info.cancerresearchuk.org/cancerstats/world/the-global-picture/>)

sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and increase the curative possibilities, an increasing number of screening programmes are being developed which target the asymptomatic or preinvasive stages of the cancer as in cervix, breast and colon or use serum tumour markers as in prostate and ovarian cancers. Genetic screening can be used to target screening to groups at most risk of developing cancer, e.g. *BRCA1* positive and breast cancer (see Table 9.3). The aim of screening programmes is to improve individual and/or population survival by detecting cancer at its very early stages when the patient is asymptomatic. This strategy is dependent upon finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

Screening is provided to populations, e.g. for breast, cervical and colon cancer in the UK, and also to individuals via

Figure 9.5 Lead time bias. Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of A + B. The actual survival time (C) remains unchanged.

annual check-ups, or opportunistic when patients see their doctor for other reasons.

Unfortunately, earlier diagnosis does not necessarily mean longer survival and randomized trials are necessary to prove benefit. With lead time bias, the patient is merely treated at an earlier date and hence the survival appears longer; death still occurs at the same time from the point of genesis of the cancer (Fig. 9.5). With length time bias, a greater number of slowly growing tumours are detected when screening asymptomatic individuals leading to a false impression of an improvement in survival.

An effective screening procedure should:

- be affordable to the healthcare system
- be acceptable to all social groups so that they attend for screening
- have a good discriminatory index between benign and malignant lesions
- show a reduction in mortality from the cancer.

Cervical cancer. The smear test is cheap and safe but requires a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia, CIN). However, developments in liquid cytology and DNA testing for human papillomavirus (HPV) may overcome this. Effective treatment for high-risk preinvasive malignant changes reduces the incidence and mortality from cervical cancer, although there are no randomized trials. Screening will continue to be required despite the introduction of vaccination against HPV infection for women before they become sexually active because the lag time between infection and the appearance of disease can be in the order of 40–50 years.

Breast cancer. The UK NHS Breast Screening Programme (i.e. biplanar mammography every 3 years) for women aged 50–70 years has been shown to reduce mortality from breast cancer in randomized controlled studies. The test is acceptable to most women with 50–75% of women attending for screening when sufficiently educated about the benefits. In North America, there is continuing debate about whether annual mammography from a younger age is more effective.

The cost is estimated to be between £250 000 and £1.3 million per life saved, money which, according to critics of screening, could be used more appropriately in better treatment.

Women from families with *BRCA1*, *BRCA2* and *p53* mutations require intensive screening starting at an earlier age when mammography is inaccurate due to greater breast density and MRI scanning is preferred.

Colorectal cancer (CRC). Faecal occult blood is a cheap test for the detection of CRC. Large randomized studies have shown a reduction in cancer-related mortality of 15–33%. However, the false-positive rates are high, meaning many unnecessary colonoscopies (see p. 291). The UK has recently introduced a national screening programme using

faecal occult blood in patients aged 60–64 years, in which positive tests have identified that 10% have cancer and 40% adenomas. A randomized trial in Norway has found an increased number of early stage cancers in the screened population but a high incidence of interval cancers between biennial screens.

Colonoscopy is the 'gold-standard' technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present and CT colonography ('virtual colonoscopy') (see Fig. 6.5) may become an alternative along with genetic testing and stool DNA tests.

Other population-based screening programmes that are being used or are in trials are:

Prostate cancer. Serum prostate-specific antigen (PSA) can be used for the detection of this cancer, which is on the increase. Many men over 70 have evidence of prostate cancer at post mortem with no symptoms of the disease and it has been suggested that over 75-year-olds should not have screening PSAs. The test must be interpreted with caution due to the natural increase in PSA with age, benign prostatic hypertrophy and with prostatitis. The early results of screening for prostate cancer have varied greatly from no benefit in a low-risk population to a halving of deaths from prostate cancer in a general population study but with no overall reduction in mortality. Currently national screening programmes are not recommended.

Epithelial ovarian cancer. Serum CA125 can be used for the early detection of this cancer and is the subject of ongoing trials. An improvement in survival of a screened population can be shown but at the cost of many unnecessary laparotomies so that further enhancements are being investigated by serial testing and in combination with transvaginal ultrasound scans.

The symptomatic patient with cancer

Patients may offer information of predisposing conditions and family history that alerts the clinician to the likelihood of a cancer diagnosis. Many present with a history of tumour site-specific symptoms, e.g. pain, and physical signs, e.g. a mass, which readily identify the primary site of the cancer. However, some only seek medical attention when more systemic and nonspecific symptoms occur such as weight loss, night sweats, fever, fatigue, recurrent infections and anorexia. These usually indicate a more advanced stage of the disease, except in some paraneoplastic and ectopic endocrine syndromes (see below). Other patients are only diagnosed upon the discovery of established metastases such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer or the liver enlargement of metastatic gastrointestinal cancer (Table 9.6).

Paraneoplastic syndromes are indirect effects of cancer (Box 9.2, Fig. 9.6) that are often associated with specific types of cancer and may be reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example in the Lambert–Eaton syndrome (see p. 1152), there is cross-reactivity between tumour antigens and the normal tissues, e.g. the acetylcholine receptors at neuromuscular junctions.

The **coagulopathy of cancer** may present with thrombophlebitis, deep venous thrombosis and pulmonary emboli, particularly in association with cancers of pancreas, stomach

Table 9.6 Symptoms and signs of malignant disease

Degree of spread	Anatomical location	Examples of clinical problems
Local	Mass	Thyroid nodule, pigmented naevus, breast lump, abdominal mass, testicular mass
	Local infiltration of skin	Dermal nodules, peau d'orange, ulceration
	Local infiltration of nerve	Neuropathic pain and loss of function
Nodal	Local infiltration of vessel	Horner's, cord compression, pancoast tumour, focal CNS deficit, hypopituitarism
	Obstruction of viscera or duct	Venous thrombosis, tumour emboli, haemorrhage, e.g. GI
		Small or large bowel obstruction, dysphagia, SVC obstruction
Metastatic		Obstructive uropathy, acute kidney injury, urinary retention, stridor, lobar collapse, pneumonia, cholestatic jaundice
	Peripheral	Supraclavicular fossa, Virchow's node, lymphoedema
	Central	Mediastinum – SVC obstruction, porta hepatis – obstructive jaundice, para-aortic nodes and back pain
	Lung	Pleuritic pain, cough, shortness of breath, lymphangitis and respiratory failure, recurrent pneumonia
	Liver	RUQ pain, anorexia, fever, raised serum liver enzymes, jaundice
	Brain	Headache and vomiting of raised intracranial pressure, focal deficit, coma, seizure
	Bone	Bone pain, cord compression, fracture, hypercalcaemia
	Pleura	Effusion, pain, shortness of breath
	Peritoneum	Ascites, Krukenberg tumours
	Adrenal	Addison's disease (hypoadrenalism)
	Umbilicus	Sister Mary Joseph's nodule

Box 9.2 Paraneoplastic syndromes

Syndrome	Tumour	Serum antibodies
Neurological		
Lambert-Eaton syndrome	Lung (small-cell) lymphoma	Anti-VGLC
Peripheral sensory neuropathy	Lung (small-cell), breast and ovary lymphoma	Anti-Hu
Cerebellar degeneration	Lung (particularly small-cell) lymphoma	Anti-Yo
Opsoclonus/myoclonus	Breast, lung (small-cell)	Anti-Ri
Stiff person syndrome	Breast, lung (small-cell)	Anti-amphiphysin
Limbic, hypothalamic, brain stem encephalitis	Lung	Anti-Ma protein
	Testicular	Anti-NMDAR
Endocrine/metabolic		
SIADH	Lung (small-cell)	
Ectopic ACTH secretion	Lung (small-cell)	
Hypercalcaemia	Renal, breast, myeloma, lymphoma	
Fever	Lymphoma, renal	
Musculoskeletal		
Hypertrophic pulmonary osteoarthropathy	Lung (non-small-cell)	
Clubbing	Lung	
Skin		
Dermatomyositis/polymyositis	Lung and upper GI	
Acanthosis nigricans	Mainly gastric	
Velvet palms	Gastric, lung (non-small cell)	
Hyperpigmentation	Lung (small-cell)	
Pemphigus	Non-Hodgkin's lymphoma, CLL	
Haematological		
Erythrocytosis	Renal cell carcinoma, hepatocellular carcinoma, cerebellar haemangioblastoma	
Thrombocytosis	Ovarian cancer	
Migratory thrombophlebitis	Pancreatic adenocarcinoma	
DVT	Adenocarcinoma	
DIC	Adenocarcinoma	
Renal		
Nephrotic syndrome	Myeloma, amyloidosis	
Membranous glomerulonephritis	Lymphoma	

SIADH, syndrome of inappropriate antidiuretic hormone secretion; ACTH, adrenocorticotrophic hormone; CLL, chronic lymphocytic leukaemia; DIC, disseminated intravascular coagulation; NMDAR, N-methyl-D-aspartate receptors.

and breast. Some 18% of patients with recurrent pulmonary embolus will be found to have an underlying cancer and many cancer patients are at increased risk of venous thromboembolism (VTE) following diagnosis. Trousseau's syndrome – superficial thrombophlebitis migrans – refers to this process in the superficial venous system. All patients with

active cancer admitted to hospital are at high risk of VTE and should be given prophylaxis with subcutaneous LMW heparin in the absence of any contraindications (see p. 429). Dabigatran, an oral direct thrombin inhibitor, is an alternative therapy.

Other symptoms are related to peptide or hormone release, e.g. carcinoid or Cushing's syndrome.

Fearon KCH. Cancer cachexia and fat-muscle physiology. *N Engl J Med* 2011; 365:565–567.

Figure 9.6 Paraneoplastic peripheral neuropathy with wasting of small muscles of the hands.

Table 9.7 Serum tumour markers

α -Fetoprotein	Hepatocellular carcinoma and non-seminomatous germ cell tumours of the gonads
β -Human chorionic gonadotrophin (β -hCG)	Choriocarcinomas, germ cell tumours (testicular) and lung cancers
Prostate-specific antigen (PSA)	Carcinoma of prostate
Carcinoma embryonic antigen (CEA)	Gastrointestinal cancers
CA125	Ovarian cancer
CA19-9	Gastrointestinal cancers, particularly pancreatic cancer
CA15-3	Breast cancer
Osteopontin	Many cancers including mesothelioma
M-band (Ig or light chain)	Myeloma, chronic lymphocytic leukaemia, small lymphocytic lymphoma, lymphoplasmacytic lymphoma, amyloid

Cachexia of advanced cancer is thought to be due to release of chemokines such as tumour necrosis factor (TNF), as well as the fact that patients have a loss of appetite. The unexplained loss of >10% of body weight in a patient should always stimulate a search for an explanation.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster and tuberculosis.

Serum tumour markers

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Table 9.7. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology as these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment. As discussed in subsequent sections, a proportion of low-grade B-cell lymphomas and a majority of cases of myeloma will produce a monoclonal paraprotein of intact immunoglobulin molecule or light chains. This acts

as a valuable tumour marker in the diagnosis and assessment of response.

Cancer imaging

Radiological investigation by experts is required at various stages: at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence and for the diagnosis and treatment of complications.

The choice of investigations needs to be guided by the patient's symptoms and signs, site and histology of the cancer, the curative or palliative potential of treatment and the utility of the information in guiding treatment. The investigations are described under each tumour type.

Contrast agents are used for increased structural discrimination and can be further enhanced with functional specificity for metabolically active tissue with 19fluorodeoxy-glucose uptake and CT-positron emission tomography (CT-PET scan) as used extensively in head and neck cancer, lung cancer and lymphoma. *Radionuclide imaging* of sentinel lymph nodes is used to guide lymphatic surgery in breast cancer and melanoma. Tumour targeted contrast agents can improve detection rates such as the radiolabelled MAb rituximab for lymphoma or radiolabelled small molecules such as octreotide for neuroendocrine tumours. Research into the use of reporter agents which become visible only upon activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

Biopsy and histological examination

The diagnosis of cancer may be suspected by both patient and doctor but advice about treatment can usually only be given on the basis of a tissue diagnosis. This may be obtained by endoscopic, radiologically-guided or surgical biopsy or on the basis of cytology (e.g. lung cancer diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign ones by the pleiomorphic nature of the cells, increased numbers of mitoses, nuclear abnormalities of size, chromatin pattern and nucleolar organization and evidence of invasion into surrounding tissues, lymphatics or vessels. The degree of differentiation (or conversely of anaplasia) of the tumour has prognostic significance: generally speaking, more differentiated tumours have a better prognosis than poorly-differentiated ones. In some tumours where the surgical procedure will vary depending on the presence of malignancy, an intraoperative histological opinion can be rapidly obtained using a tissue sample processed using 'frozen section' techniques, which requires the availability of a histopathologist. This obviates the need for the sample to be paraffin embedded, which takes hours to days.

Tissue tumour markers. Immunocytochemistry, using monoclonal antibodies against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours and between some subsets of these, for example T- and B-cell lymphomas, germ cell tumours, prostatic tumours, neuroendocrine tumours, melanomas and sarcomas. However, there is much overlap in the expression of many of the markers and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

Molecular markers of genetic abnormalities have long been available in the haematological cancers and are increasingly available in solid cancers. For example, **fluorescent in situ hybridization** (FISH, see p. 40) can be used to look for characteristic chromosomal translocations, e.g. in lymphoma and leukaemia, as well as deletions or amplifications, e.g. in breast cancer (see genetic basis of cancer, p. 45). **Tissue**

Reactivated herpes zoster (Shingles).

microarrays can identify patterns of multiple genomic alterations and single nucleotide polymorphisms (SNPs), e.g. in breast cancer and lymphoma (see p. 35), and **RNA assays** with RT-PCR can be used to identify tissue of origin with prognostic and predictive relevance.

Genomics and proteomics are being investigated in order to target new (and expensive) therapies, e.g. imatinib in CML and GIST, trastuzumab and lapatinib in breast cancer and erlotinib in lung cancer.

CANCER TREATMENT

Aims of treatment

Optimal cancer treatment is delivered by a multidisciplinary team which coordinates the delivery of the appropriate anti-cancer treatment (surgery, chemotherapy, radiotherapy and biological/endocrine therapy), supportive and symptomatic care and psychosocial support. While all members will have the patient's care as their central concern, someone, often the oncologist, has to take responsibility for the coordination of the many professionals involved.

The organization across multiple departments and coordination from primary to secondary and tertiary care has become known as a patient pathway. Establishment of agreed patient pathways has enabled more effective and timely delivery of care and post-treatment rehabilitation. The aim is to provide optimal treatment and for the patient to experience seamless and high quality care and to allow audit and continuing improvement against agreed standards. Central to this endeavour is the involvement of the patient, through education as to the nature of their disease and the treatment options available. An informed choice can then be made, even if in the end it is simply to abide by the decisions made by the professionals. Good communication embodies a humane approach which preserves hope at an appropriate level through empathy and understanding of the patient's position (see p. 14).

A curative approach

For most solid tumours local control is necessary, but not sufficient, for cure because of the presence of systemic (microscopic) disease, while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent upon earlier detection to increase the success of local treatment and effective systemic treatment. The likelihood of cure of the systemic disease depends upon the type of cancer and its expression of appropriate treatment targets, its drug sensitivity and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured, e.g. leukaemia, lymphoma, gonadal germ cell tumours and choriocarcinoma. For most common solid tumours such as lung, breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy (see below) after surgery can be cured in 10–20% of patients.

Adjuvant therapy for solid tumours

This is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, following treatment given for the primary lesion. '*Neoadjuvant*' therapy, alternatively, is

given before primary surgery, to both shrink the tumour to improve the local excision and treat any micrometastases as soon as possible.

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in 10^6) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, e.g. differentiation, invasion of blood vessels or regional lymph nodes and molecular markers, e.g. Her2 in breast cancer, enable risk stratification and increasing individualization of therapy.

The success of adjuvant treatment across many tumour types relies upon careful selection of patients according to defined risk criteria and the reduction of treatment toxicity to reach a balanced risk/benefit ratio. Relative risk reductions in the order of 12–33% and absolute improvements in 5–10-year survival of 5–25% (dependent upon the pre-existing risk) have been achieved in common epithelial cancers such as lung, bowel, breast and prostate, with greater absolute improvements in the more sensitive germ cell tumours.

While these improvements currently translate into many lives saved from common diseases at a public health level, the majority who receive such treatment do not benefit because they were already cured, or because the cancer is resistant to the treatment. Better tests, e.g. gene arrays and circulating tumour cells, are being developed to identify those with the micrometastases who really need treatment. On an individual patient basis the decision on whether adjuvant treatment will be worthwhile must include consideration of other factors such as the patient's life expectancy, concurrent medical conditions and lifestyle priorities.

A palliative approach

When cure is no longer possible, palliation, i.e. relief of tumour symptoms, preservation of quality of life and prolongation of life, is possible in many cancers in proportion to their drug and radiation sensitivity. There is on average a 2–18-month prolongation in median life expectancy with treatments for solid tumours (see specific tumour types for details) and up to 5–8 years for some leukaemias and lymphomas, with those with the most responsive tumours experiencing the greatest benefit. The development of more effective chemotherapeutic drugs, targeted biological agents and better supportive care has done much to reduce the side-effects of systemic therapy and to improve the cost/benefit ratio for the patient receiving palliative treatment. In addition, through early assessment during treatment, it is possible to stop if no evidence of benefit is demonstrable early on, so as to minimize exposure to toxic and unsuccessful treatment.

Assessments before treatment

Staging

Before a decision about treatment can be made, not only the type of tumour but also its extent and distribution need to be established. Various 'staging investigations' are therefore performed before a treatment decision is made. To be useful clinically the staging system must subdivide the patients into groups of different prognosis which can guide treatment selection.

The staging systems vary according to the type of tumour and may be site specific (see *Hodgkin's lymphoma*, p. 461),

Table 9.8 Eastern Cooperative Oncology Group (ECOG) performance status scale

Status	Description
0	Asymptomatic, fully active and able to carry out all predisease performance without restrictions
1	Symptomatic, fully ambulatory but restricted in physically strenuous activity and able to carry out performance of a light or sedentary nature, e.g. light housework, office work
2	Symptomatic, ambulatory and capable of all self-care but unable to carry out any work activities. Up and about >50% of waking hours: in bed <50% of day
3	Symptomatic, capable of only limited self-care, confined to bed or chair >50% of waking hours, but not bedridden
4	Completely disabled. Cannot carry out any self-care. Totally bedridden

or the TNM (tumour, node, metastases) classification shown in Table 15.29, which can be adapted for application to most common cancers.

Performance status

In addition to anatomical staging, the person's age and general state of health need to be taken into account when planning treatment. The latter has been called 'performance status' and is of great prognostic significance for all tumour types (Table 9.8). Performance status reflects the effects of the cancer on the patient's functional capacity. An alternative performance rating scale is by Karnowsky. With a performance status of 2, response to and survival following treatment are greatly reduced for most tumour types.

Assessing the benefits of treatment

A measurable response to treatment can serve as a useful early surrogate marker when assessing whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of early stage disease

Response to treatment can be subjective or objective.

A subjective response is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms (Patient Reported Outcome Measures, PROMs) form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

An objective response to treatment is assessed clinically and radiologically. The term '*remission*' is often used synonymously with '*response*', which if complete, means an absence of detectable disease without necessarily implying a cure of the cancer. The terms used to evaluate the responses of tumours are given in Box 9.3. For a complete response all previous clinical abnormalities should have resolved and this needs to be confirmed by clinical examination or sampling of the primary disease site, e.g. by bone marrow examination in leukaemia. Where a tumour marker exists, such as a paraprotein in myeloma or β -hCG in testicular cancer, reductions in

Box 9.3 RECIST criteria for assessing response to treatment

Complete response	Disappearance of all target lesions
Partial response	$\geq 30\%$ decrease in the baseline sum of the longest diameters of all target lesions
Progression	$\geq 20\%$ increase in the sum of the longest diameters of all target lesions compared with the smallest recorded sum since treatment started, or the appearance of any new lesions
Stable disease	All values between partial response and progressive disease
Target lesions	Measurable lesions up to 5 per organ and 10 in total, selected on size and replicable measurement
Non-target lesions	Non-measurable lesions recorded as present or absent at baseline and on follow-up.
Measurable	Lesions with the longest diameter in one dimension ≥ 2.0 cm or ≥ 1.0 cm if assessed by spiral CT scan
Non-measurable	e.g. bone, meningeal, ascites, pleural effusion, inflammatory breast cancer, lymphangitis cutis and pulmonis, cystic lesions

the level of tumour markers are useful surrogates for evidence of tumour response. They are also useful predictors for disease recurrence. Radiologically, a complete response, is the complete disappearance of all detectable disease and a partial response, defined since 1999 by the Response Evaluation Criteria in Solid Tumors (RECIST) convention, is a $\geq 30\%$ reduction in the sum of all measurable lesion diameters.

The final assessment of treatment outcome is the impact of the therapy on remission duration and survival, i.e. the cure rate. Such survival figures are increasingly incorporating quality of life assessments and a health economic assessment to calculate the number of quality adjusted life years (QALY) gained for the cost of the treatment and judgements made about health system affordability.

When counselling, the individual patient's interpretation of the trial evidence for benefit must be adjusted for the degree to which they resemble the population from which it is derived and the cost interpreted in view of their co-morbidities and lifestyle choices.

PRINCIPLES OF CHEMOTHERAPY

Cytotoxic chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and sometimes frank necrosis. Different cytotoxic drugs work at different stages in the cell cycle (Fig. 9.7; see also Fig. 2.13).

There is a narrow therapeutic window between effective treatment of the cancer and normal tissue toxicity, because cytotoxic drugs are not cancer specific (unlike some of the targeted biological agents) and the increased proliferation in cancers is not much greater than in normal tissues (see tumour growth and failure of apoptosis, p. 32, 33). The dose and schedule of the chemotherapy is limited by the normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending upon the

a

Chemotherapy radiological response. Bone metastasis responding to chemotherapy with sclerotic new bone formation. (a) Tumour (arrow). (b) Following radiotherapy.

Figure 9.7 Cell cycle (see also Fig. 2.13) and chemotherapy drugs.

pharmacokinetics of the drug and affinity for particular tissues (e.g. heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms which seek to exploit differences between normal and transformed cells. While most of the drugs have been derived in the past by empirical testing of many different compounds, e.g. alkylating agents, the new molecular biology is leading to targeting of particular genetic defects in the cancer (see tyrosine kinase inhibitors, p. 445).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by the infusion of stem cell preparations to diminish myelotoxicity. The use of more specific targeted biological agents with relatively weak pro-apoptotic effects in combination with the general cytotoxics has also improved the therapeutic ratio (see trastuzumab and breast cancer, p. 475). Certain cytotoxic therapies may also be administered into the pleural space, the peritoneum, the CSF or into the arterial supply of a tumour.

Most tumours rapidly develop resistance to single agents given on their own through changes in membrane transport and DNA repair pathways. For this reason, the principle of intermittent combination chemotherapy was developed. Several drugs are combined together, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days, followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 9.8).

In many experimental tumours, it has been shown that there is a log-linear relationship between drug dose and number of cancer cells killed and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that

Figure 9.8 Effects of multiple courses of cytotoxic chemotherapy, showing the decrease in the number of cells with each course.

where cure is a realistic option the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold, but not cause undue toxicity, is required as the short-term quality of life becomes a major consideration.

Classification of cytotoxic drugs (Table 9.9)

DNA damaging drugs

Alkylating agents act by covalently binding alkyl groups and their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Despite being among the earliest cytotoxic drugs developed, they maintain a central position in the treatment of cancer. Melphalan is one of the original nitrogen mustards and is used in multiple myeloma. Chlorambucil is used in Hodgkin's lymphoma and chronic lymphocytic leukaemia. Other common alkylating agents include cyclophosphamide and ifosfamide,

Table 9.9 Chemotherapy: some cytotoxic drugs

DNA damaging
Free radicals – alkylators, e.g. cyclophosphamide
DNA cross-linking – platinum, e.g. cisplatin, carboplatin, oxaliplatin
Antimetabolites
Pyrimidine synthesis, e.g. 5-fluorouracil, capecitabine, cytarabine, gemcitabine
Purine, e.g. mercaptopurine, thioguanine, fludarabine
Antifolates, e.g. methotrexate, pemetrexed
DNA repair inhibitors
Topoisomerase-I inhibitors, e.g. irinotecan
Topoisomerase-II inhibitors, e.g. etoposide
DNA intercalation – anthracyclines, e.g. doxorubicin
Antitubulin
Tubulin binding – alkaloids, e.g. vincristine, vinorelbine; Taxanes, e.g. paclitaxel, docetaxel

as well as the nitrosoureas, carmustine (BCNU), bendamustine, lomustine (CCNU) and busulfan used in chronic myeloid leukaemia. Tetrazines also alkylate DNA; dacarbazine is used in Hodgkin's lymphoma and temozolomide in malignant gliomas.

Platinum compounds. Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer (cisplatin) and have a major role against many other tumours, including lung, ovarian and head and neck (cis or carboplatin) and gastrointestinal (oxaliplatin) cancer. Toxicity, as for other heavy metals, includes renal and peripheral nerve damage.

Antimetabolites

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways. Antimetabolites can be divided into:

Folic acid antagonists, e.g. methotrexate. This is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to 'rescue' normal tissues from the effects of high doses of methotrexate.

Pyrimidine antagonists. 5-Fluorouracil (5FU) consists of a uracil molecule with a substituted fluorine atom. It acts by blocking the enzyme thymidylate synthase, which is essential for pyrimidine synthesis. 5-Fluorouracil has a major role in the treatment of solid tumours, particularly gastrointestinal cancers. Oral capecitabine is metabolized to 5FU and tegafur with uracil and calcium folinate are used in gastrointestinal and breast cancers.

Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytosine arabinoside (cytarabine, Ara-C) is used almost exclusively in the treatment of acute myeloid leukaemia where it remains the backbone of therapy, while its analogue gemcitabine is proving useful in a number of solid cancers such as lung, breast, pancreas and ovary. Fludarabine is used in the treatment of B cell chronic lymphocytic leukaemia; it is also used in reduced intensity stem cell transplantation (see this chapter) because of its immunosuppressive effect. Other related drugs have found niche applications in acute leukaemia (cladribine, clofarabine, nelarabine/AraG) and myelodysplasia (azacytidine).

Purine antagonists, e.g. 6-mercaptopurine and 6-thioguanine, which are both used almost exclusively in the treatment of acute leukaemia.

Table 9.10 Side-effects of chemotherapy

Common
Nausea and vomiting
Hair loss
Myelosuppression
Mucositis
Fatigue
Drug-specific
Cardiotoxicity, e.g. anthracyclines
Pulmonary toxicity, e.g. bleomycin
Neurotoxicity, e.g. cisplatin, vinca alkaloids, taxanes
Nephrotoxicity, e.g. cisplatin
Skin plantar-palmar dermatitis, e.g. 5-fluorouracil
Sterility, e.g. alkylating agents, anthracyclines, docetaxel
Secondary malignancy, e.g. alkylating agents, epipodophyllotoxins
CNS, e.g. tyrosine kinase inhibitor sunitinib

DNA repair inhibitors

Epipodophyllotoxins. These are semisynthetic derivatives of podophyllotoxin which inhibit topoisomerase. Topoisomerase enzymes allow unwinding and uncoiling of supercoiled DNA. Etoposide is a drug used in a wide range of cancers and works by maintaining DNA strand breaks by inhibiting the enzyme topoisomerase II. Topoisomerase I inhibitors such as irinotecan and topotecan have also proved active against lung, colon, ovary and cervix cancer.

Cytotoxic antibiotics. The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase II DNA repair. They have a wide spectrum of activity in haematological and solid tumours. Doxorubicin and its congener epirubicin are two of the most widely used of all cytotoxic drugs but have cumulative toxicity to the myocardium. Pegylated liposomal doxorubicin is used for Kaposi's sarcoma and as second-line treatment for advanced ovarian cancer with reduction of cardiotoxicity, but increased toxicity to the skin on the palms of the hands and soles of the feet. Amisacrine is a similar drug used occasionally in acute myeloid leukaemia. Bleomycin and mitomycin are also intercalating agents which promote the cleavage of DNA and RNA. Bleomycin has a particular toxicity to the lung causing interstitial fibrosis.

Antitubulin agents

Vinca alkaloids. Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation during mitosis (see p. 20). They are used in the treatment of haematological (vincristine and vinblastine) and non-haematological cancers (vinorelbine). They are associated with neurotoxicity due to their anti-microtubule effect and must never be given intrathecally as this is lethal.

Taxanes. Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules. They are active drugs against many cancers such as ovarian, breast and lung cancer. Taxanes can cause neurotoxicity and hypersensitivity reactions and patients should be premedicated with steroids, H1 and H2 histamine antagonists prior to treatment.

Side-effects of chemotherapy

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners; however, an appreciation of its common potential side-effects is necessary for any general physician who is called to see a cancer patient on chemotherapy. The five most common side-effects are vomiting, hair loss, tiredness, myelosuppression and mucositis (Table 9.10). Side-effects are much more directly dose related than anticancer effects and it has been

Table 9.11 Some common chemotherapy regimens

Hodgkin's lymphoma	ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
Non-Hodgkin's lymphoma	CHOP	Cyclophosphamide, hydroxy-doxorubicin, vincristine, prednisolone
Breast	AC	Adriamycin and cyclophosphamide
Lung	PE	Cisplatin, etoposide
Stomach	ECF	Epirubicin, cisplatin, 5-fluorouracil
Colorectal	FolFOX	Oxaliplatin, 5FU, folinic acid

Note: Some abbreviations are related to trade names.

the practice to give drugs at doses close to their maximum tolerated dose, although this is not always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in Table 9.11.

Extravasation of intravenous drugs. Cytotoxic drugs should only be given by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. Stop the infusion immediately and institute local measures, e.g. aspirate as much of the drug from the cannula, infiltrate area with 0.9% saline and apply warm compresses. Antihistamines and corticosteroids may give symptomatic relief. Dexrazoxane is used for anthracycline extravasation.

Nausea and vomiting. The severity of this common side-effect varies with the cytotoxic and it can be eliminated in 75% of patients by using modern antiemetics. Nausea and vomiting are particular problems with platinum analogues. A stepped policy with antiemetics such as metoclopramide and domperidone followed by 5-HT₃ serotonin antagonists (e.g. ondansetron, granisetron) combined with dexamethasone should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is used with dexamethasone and a 5-HT₃ antagonist. Drugs such as cyclizine, haloperidol and levomepromazine and benzodiazepines can be used to control persistent nausea.

Hair, skin and nails. Many but not all cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but in general this side-effect can only be avoided by selection of drugs where this is possible. Hair regrows on completion of chemotherapy. Nails will demonstrate banding reflecting periods of cessation of growth during each chemotherapy cycle and skin toxicity may be particularly pronounced with 5FU, capecitabine and docetaxel (Fig. 9.9).

Fatigue is often significant and may continue beyond completion of therapy. Other problems such as anaemia or depression may exacerbate this. Attention should be paid to nutrition, hydration, sleep hygiene, gentle exercise, task prioritization, pacing, realistic target setting and scheduling rest within the day.

Bone marrow suppression and immunosuppression. Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon (Fig. 9.10). Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions. (Neutropenic infection is discussed on p. 448.) The risk of infective problems can be ameliorated by the use of prophylactic antimicrobials, such as ciprofloxacin, or the use of G-CSF as primary prophylaxis in those chemotherapy regimens with a significant risk of febrile neutropenia or those patients on less intensive therapies who are at higher risk due to age or co-morbidity.

**Figure 9.9** Hands showing palmar-plantar skin toxicity.**Figure 9.10** Cyclical myelosuppression from chemotherapy (arrows).

Mucositis. This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. It causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. Mucositis can be generalized throughout the intestinal tract when it can cause life-threatening diarrhoea. Treatment is with antiseptic and anti-candidal mouthwash and, if severe, fluid and antibiotic support, as the mucosa is a portal for entry of enteric organisms. Palifermin, a recombinant keratinocyte derived growth factor, may ameliorate severe chemotherapy and radiotherapy induced mucositis.

Anthracycline dilated cardiomyopathy with congestive heart failure.

Other toxicities

Cardiotoxicity. This is a rare side-effect of chemotherapy, usually associated with anthracyclines such as doxorubicin, and can present as an acute arrhythmia during administration or cardiac failure due to cardiomyopathy after chronic exposure. This effect is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m² body surface area cumulative doxorubicin dose). The risk of anthracycline cardiomyopathy is also dependent on other treatments such as trastuzumab or radiotherapy as well as other cardiac risk factors such as hypertension, smoking and hypercholesterolaemia. Cardiotoxicity can also be reduced by using the analogue epirubicin or by reducing peak drug concentrations through delayed release preparations such as liposomal doxorubicin. 5-Fluorouracil and its prodrug capecitabine can cause cardiac ischaemia.

Neurotoxicity. This occurs predominantly with the vinca alkaloids, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which once established is only partially reversible. Vinca alkaloids such as vincristine must never be given intrathecally as the neurological damage is progressive and fatal.

Nephrotoxicity. Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules and careful monitoring of renal function.

Sterility and premature menopause. Some anticancer drugs, particularly alkylating agents, but also anthracyclines and docetaxel, may cause gonadal damage resulting in sterility and in women the loss of ovarian oestrogen production, which may be irreversible.

In males, the storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent.

In females, collection of oocytes to be fertilized *in vitro* and cryopreserved as embryos for subsequent implantation is most successful; however it is also possible to collect and freeze by vitrification of unstimulated oocytes. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization is still experimental. The recovery of gonadal function is dependent upon the status before treatment and in women this is mostly related to age since menarche, with those under the age of 40 having significantly more ovarian reserve.

Secondary malignancies. Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines and epipodophyllotoxins are particularly implicated in this complication.

Haemopoietic stem cell transplantation (HSCT)

HSCT is used in a range of malignancies and some non-malignant disorders such as sickle cell disease. It relies on the ability of transfused haemopoietic stem cells to repopulate the marrow niche that has been rendered temporarily or permanently hypoplastic from chemotherapy with or without additional radiotherapy. Such procedures

Box 9.4 Sources of stem cells

- Bone marrow or peripheral blood stem cells
 - Autologous – from patient
 - Syngeneic – from identical twin
 - Allogeneic
 - related or unrelated donor
 - full (10/10) or partial (8 or 9/10) HLA-match
 - Umbilical cord blood

vary in the source of the stem cells and in the type and intensity of the preparatory conditioning regimen (Box 9.4).

Autologous stem cell transplantation

Most anticancer drugs have a sigmoid dose-response relationship which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing cytotoxic drug dose is often not possible, owing to toxicity. For those chemotherapeutic agents with a dose-limiting toxicity of bone marrow failure, infusion of previously harvested haemopoietic stem cells is able to 'rescue' the haemopoietic system and permits the use of higher doses to overcome tumour drug resistance. Haemopoietic stem cells are either collected from the patient's bone marrow, or more commonly by leucopheresis from the peripheral blood following stem cell mobilization from the marrow niche by the administration of the growth factor granulocyte colony-stimulating factor (G-CSF) with or without chemotherapy. These stem cells are stored by cryopreservation and then reinfused intravenously after an intensive, chemotherapy regimen. This approach has been particularly effective in relapsed leukaemias, lymphomas, myeloma and germ cell tumours. However, tumour contamination of the reinfused stem cells remains a reality. Treatment-related mortality is in the region of 1–5%. Such an approach is also being evaluated for the treatment of severe autoimmune disease, such as Crohn's.

Allogeneic stem cell transplantation

Conventional ablative allogeneic transplants

These combine the cytotoxic effect of high-dose therapy with a potent immunotherapy effect. Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy with or without radiotherapy with the dual effects of treating the malignancy as well as causing temporary immunosuppression that allows the graft 'to take'. Donors are usually fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors than unrelated volunteers. Allogeneic transplantation has been successfully used in acute and chronic leukaemias and myeloma. The engraftment of the donor immune system, with antitumour activity (graft-versus-tumour), is primarily responsible for the increased effectiveness of this approach. Complications include graft-versus-host disease (GVHD), an allo-immune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal in some cases. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (ciclosporin or tacrolimus) given to prevent graft-versus-host disease, results in a high incidence of opportunistic infection and viral reactivation, e.g. CMV. All patients receive prophylactic antibacterial, antifungal and antiviral drugs. Mortality therefore from conventional allogeneic stem cell transplantation is a major problem, with 20–40% at risk of dying from the procedure,

depending on the age and status of the recipient and the degree of HLA compatibility of the donor. The use of donor lymphocyte infusions following allogeneic bone marrow transplantation (BMT), while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy via graft-versus-tumour activity with clinical remissions observed, albeit with a risk of triggering GVHD.

Non-myeloablative allogeneic stem cell transplantation

This has been developed using conditioning therapy containing drugs such as fludarabine which are primarily immunosuppressive rather than myelosuppressive. This maintains the anticancer 'graft-versus-leukaemia' effect of the transplant without the toxicity of conventional allogeneic stem cell transplantation. Treatment-related mortality is lower and the technique can be used successfully particularly in the elderly and those with co-morbidities. GVHD remains an obstacle to success however.

PRINCIPLES OF ENDOCRINE THERAPY

Oestrogens are capable of stimulating the growth of breast and endometrial cancers and androgens the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer and provides a minimally toxic non-curative (palliative) treatment in advanced/metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However, this is also modified by the many molecular interactions between the activation pathways of, for example, EGFR and oestrogen receptor (ER). (See breast cancer p. 475 and prostate cancer p. 481.)

PRINCIPLES OF BIOLOGICAL AND TARGETED THERAPY

Biological therapies

Interferons

Interferons are naturally occurring cytokines that mediate the cellular immune response. They are both antiproliferative and stimulate humoral and cell-mediated immune responses to the tumour that can result in an antitumour effect if the host effector mechanisms are fully competent.

Alpha-interferon (IFN- α) has been used to treat advanced melanoma and renal cell carcinoma.

Treatment with IFN has side-effects (see p. 321), most commonly flu-like symptoms, which tend to diminish with time, and fatigue, which generally does not, and can be treatment limiting. IFN was given as a daily subcutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.

Interleukins

Interleukin 2, a recombinant protein, is used to activate T-cell responses, often in conjunction with interferon-stimulated B-cell activation. Antitumour activity has been observed in renal cell carcinoma and melanoma with responses in

10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely this includes the capillary leak syndrome with hypotension and pulmonary oedema, while autoimmune thyroiditis and vitiligo occur later.

Immunotherapy

While the most dramatic evidence for immunotherapy is seen in the allogeneic HSCT above, activation of the immune system using Bacille Calmette–Guérin (BCG) for bladder cancer induces responses in 60% of patients. Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from B-cell lymphomas, or melanoma antigens, have been used as tumour vaccines together with manipulation of the immune system to overcome tolerance.

Immunomodulatory drugs (IMiDs) thalidomide, lenalidomide

This family of immunomodulatory drugs are being increasingly used in a range of malignancies, such as myeloma, chronic lymphocytic leukaemia (CLL) and myelodysplastic syndrome (MDS) as well as some solid tumours. They have anti-angiogenic functions as well as affecting cytokine production, tumour/stromal interactions and T-cell co-stimulatory functions. They are all considered teratogenic and should be avoided in women of reproductive potential unless extra precaution is taken against conceiving.

Proteasome inhibitors

The proteasome degrades redundant or damaged proteins that have been labelled by a process called ubiquitination. Such proteins include cyclins and cyclin-dependent kinases as well as factors in the NF κ B pathway. Inhibition of the proteasome leads to apoptosis in cancer cells and is synergistic with other treatments such as steroids and chemotherapy. Bortezomib is the first of such inhibitors to reach clinical practice and is used in myeloma as well as some types of NHL.

Targeted therapies

Monoclonal antibodies

Monoclonal antibodies (MAb) directed against tumour cell surface antigens are 'humanized' by being genetically engineered and have a range of functions:

- As direct treatment for B cell lymphoid malignancy (e.g. rituximab anti-CD20 surface antigen). Tumour cell lysis occurs by both complement- and antibody-dependent cellular cytotoxicity
- As a carrier molecule to target toxins or radioisotopes to the tumour cells, e.g. anti-CD20 conjugated to radioactive yttrium or iodine has been used as treatment for non-Hodgkin's lymphoma
- As anti-growth factor agents added to chemotherapy. They act by inhibiting dimerization of the extracellular receptor molecules, e.g. trastuzumab and pertuzumab target a member of the epidermal growth factor receptor (EGFR) family, the Her2/Neu or c-erbB2 antigen to increase the apoptotic response to cytotoxics in breast cancer. Others include bevacizumab anti-VEGF receptor in colorectal and breast cancer, cetuximab anti-EGFR for head and neck and colorectal cancers and ipilimumab for melanoma.

Side-effects are those of hypersensitivity to the foreign protein and specific cross-reactivities, e.g. trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule and cetuximab for the skin follicles.

Table 9.12 Targeted therapies in cancer*

Gene	Genetic alteration	Tumour type	Therapeutic agent
Receptor tyrosine kinase			
EGFR	Mutation, amplification	Lung cancer, glioblastoma	Gefitinib, erlotinib
ERBB2	Amplification	Breast cancer	Lapatinib
FGFR1	Translocation	Chronic myeloid leukemia	PKC412, BIBF-1120
FGFR2	Amplification, mutation	Gastric, breast, endometrial cancer	PKC412, BIBF-1120
FGFR3	Translocation, mutation	Multiple myeloma	PKC412, B1BF-1120
PDGFRA	Mutation	Glioblastoma, gastrointestinal stromal tumor	Sunitinib, sorafenib, imatinib
PDGFRB	Translocation	Chronic myelomonocytic leukemia	Sunitinib, sorafenib, imatinib
ALK	Mutation or amplification	Lung cancer, neuroblastoma, anaplastic large-cell lymphoma	Crizotinib
c-MET	Amplification	Gefitinib-resistant non-small-cell lung cancer, gastric cancer	Crizotinib, XLIS4, SU11274
IGF1R	Activation by insulin-like growth	Colorectal, pancreatic cancer	CP-751, 871, AMG479
c-KIT	Mutation	Gastrointestinal stromal tumor	Sunitinib, imatinib
FLT3	Internal tandem duplication	Acute myeloid leukemia	Lestaurtinib, XL999
RET	Mutation, translocation	Thyroid medullary carcinoma	XL184
Non-receptor tyrosine kinase			
ABL	Translocation (BCR-ABL)	Chronic myeloid leukemia	Imatinib
JAK2	Mutation (V617F), translocation	Chronic myeloid leukemia, myeloproliferative disorders	Lestaurtinib, INCB018424
SRC	Overexpression	Non-small-cell lung cancer; ovarian, breast cancer; sarcoma	KX2-391, dasatinib, AZD0530
Serine-threonine-lipid kinase			
BRAF	Mutation (VGOOE)	Melanoma; colon, thyroid cancer	SB-590885, Vemurafenib, RAF265, XL211
Aurora A and B kinases	Overexpression	Breast, colon cancer; leukemia	MK-5108 (VX-689)
Polo-like kinases	Overexpression	Breast, lung, colon cancer; lymphoma	BI2536, GSK461364
MTOR	Increased activation	Renal-cell carcinoma	Temsirolimus (CCI-779), BEZ235
PI3K	PIK3CA mutations	Colorectal, breast, gastric cancer; glioblastoma	BEZ235
DNA damage or repair			
BRCA1 and BRCA2	Mutation (synthetic lethal effect)	Breast, ovarian cancer	Olaparib, MK-4827 (PARP inhibitors)
PARP, poly(adenosine diphosphate-ribose) polymerase.

Intracellular signal inhibitors (Table 9.12)

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors have many pharmacokinetic advantages over the MAb inhibitors. The first example was the tyrosine kinase inhibitor (TKi) imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein and c-Kit. This compound is an extremely effective treatment for chronic myeloid leukaemia and gastrointestinal stromal tumours (GIST), which are characterized by the presence of the c-Kit target. Lapatinib, which inhibits Her2, has increased survival in breast cancer. The less specific TKIs sunitinib and sorafenib which inhibit signalling by EGFR and VEGFR have proved effective in metastatic renal cancer, while erlotinib and gefitinib have shown activity in lung cancer. Vemurafenib is a kinase inhibitor and has a specificity for BRAF-V600 as used in malignant melanoma (p. 1226). Many

other similar molecules are in preclinical or early clinical development but heterogeneity within a single tumour occurs and genomic anomalies may not all be represented in a single biopsy specimen.

Gene therapy

Antisense oligonucleotides are short sequences of DNA bases which specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences, which are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the Bcl-2 oncogene has been shown to have an antitumour effect in patients with non-Hodgkin's lymphoma. Viral vectors for the transfection of tumour cells *in vivo* are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.

PRINCIPLES OF RADIATION THERAPY

Theoretical background

Radiation delivers energy to tissues, causing ionization and excitation of atoms and molecules. The biological effect is exerted through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle and through the generation of short-lived free radicals, particularly from oxygen, which damage proteins and membranes. The generation of free radicals depends upon the degree of oxygenation/hypoxia in the target tissues. This can affect the biological effect by up to threefold and is the subject of continuing research for hypoxic cell sensitizers to overcome the reduced efficacy of radiation for hypoxic tumours. Hypoxia, however, may also drive a more malignant potential further, so reduced efficacy is only part of the solution to the hypoxia problem.

The radiation effect will also depend upon the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with the distance from the source. The depth of penetration of biological tissues by the photons depends upon the energy of the beam. Low-energy photons from an 85 kV source are suitable for superficial treatments, while high-energy 35 MV sources produce a beam with deeper penetration, less dose at the initial skin boundary (skin sparing), sharper edges and less absorption by bone. Superficial radiation may be also delivered by electron beams from a linear accelerator that has had the target electrode that generates the X-rays removed.

The radiation dose is measured in Gray (Gy), where 1 Gray = 1 joule (J) absorbed per kilogram of absorbing tissue. The biological effect is dependent upon the dose rate, duration, volume irradiated and the tissue sensitivity. Sensitivity to photon damage is greatest during the G2-M phase of the cell cycle and is also dependent upon the DNA repair capacity of the cell.

Types of radiation therapy

External beam (or teletherapy) from a linear accelerator source produces X-rays. The energy is transmitted as photons and is the most commonly used form of radiotherapy. Cobalt-60 generators can also provide γ -rays and high-energy photons, but are being gradually phased out. Most external beam treatments that are given with curative intent are delivered in 1.5–2 Gy fractions daily for 5 days per week.

Fractionation is the delivery of the radiation dose in increments separated by at least 4–6 hours to try to exploit any advantage in DNA repair between normal and malignant cells.

Hyperfractionation is when more than one fraction per day is given and this approach has been shown to improve outcome in head and neck and lung cancer. The treatment can also be accelerated, i.e. the total dose is given in a shorter overall time. For example a standard curative treatment taking 6.5 weeks can be accelerated so that the same dose is delivered in 5.5 weeks. Radiation dose is thus described by three factors:

- Total dose in Gy
- Number of fractions
- Time for completion.

Brachytherapy is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume. Such techniques have been used to treat localized breast, prostatic and cervical carcinoma.

Systemic radionuclides, e.g. iodine-131, or radioisotope-labelled monoclonal antibodies (e.g. anti-CD20 for lymphoma) and hormones (e.g. somatostatin for carcinoid tumours), can be administered by intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via surface antigens or receptors.

Clinical application of radiation therapy

Radiotherapy treatment planning involves both detailed physics of the applied dose and knowledge of the biology of the cancer and whether the intention is to treat the tumour site alone, or include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects and therefore the total achievable dose. A balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects.

The cancers for which radiotherapy is usually employed in a primary curative approach, when the tumour is anatomically localized, are listed in Table 9.13, along with those in which radiotherapy has curative potential when used in addition to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms to improve quality of life or duration of survival (Box 9.5). Palliative treatment is usually given in as few fractions as possible over as short a time as possible. Radiotherapy planning, by the use of CT scanning guidance, has been complemented by the introduction of 3-dimensional planning and intensity modulated radiotherapy (IMRT) which can deliver curved dose distributions to enable an improved therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn allowing dose escalation or a reduced risk of toxicity. 4D radiotherapy planning is also becoming widely used varying radiation dose over time, e.g. the respiratory cycle during lung cancer treatment. Stereotactic focused irradiation using the γ -knife or Cyberknife can concentrate gamma radiation from multiple sources onto

Table 9.13 Curative radiotherapy treatment

Primary modality	Adjuvant to primary surgery
Retina	Lung
CNS	Breast
Skin	Uterus
Pharynx and larynx	Bladder
Cervix and vagina	Rectum
Prostate	Testis-seminoma
Lymphoma	Sarcoma

Box 9.5 Palliative benefits of radiotherapy

- Pain relief, e.g. bone metastases
- Reduction of headache and vomiting in raised intracranial pressure from CNS metastases
- Relief of obstruction of bronchus, oesophagus, ureter and lymphatics
- Preservation of skeletal integrity from metastases in weight-bearing bones
- Reversal of neurological impairment from spinal cord or optic nerve compression by metastases

Table 9.14 Side-effects of radiotherapy

Acute temporary side-effects/dependent on region being treated	
Anorexia, nausea, malaise Mucositis, oesophagitis, diarrhoea Alopecia Myelosuppression	
Late side-effects	
Skin	Ischaemia, ulceration
Bone	Necrosis, fracture, sarcoma
Mouth	Xerostomia, ulceration
Bowel	Stenosis, fistula, diarrhoea
Bladder	Fibrosis
Vagina	Dyspareunia, stenosis
Lung	Fibrosis
Heart	Pericardial fibrosis, cardiomyopathy, vasculopathy
CNS	Myelopathy
Gonads	Infertility, menopause
Second malignancies	e.g. leukaemia, cancer, e.g. thyroid
Other	Carotid artery stenosis

a small volume to generate an ablative dose for treating tumours of the CNS and isolated metastases.

Combination chemoradiotherapy

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin and 5FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus and cervix. Reduced local recurrence rates have translated into survival benefits and further research is investigating the concurrent use of biological agents (e.g. epidermal growth factor receptor inhibitors) with radiation.

Side-effects of radiotherapy

Early radiotherapy side-effects may occur within days to weeks of treatment when they are usually self-limiting but associated with general systemic disturbance (Table 9.14). The side-effects will depend upon tissue sensitivity, fraction size and treatment volume and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, e.g. bleomycin, actinomycin, anthracyclines, cisplatin and 5-fluorouracil.

Later side-effects occur from months to years later, unrelated to the severity of the acute effects because of their different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis which produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue.

Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

Secondary malignancies following radiotherapy may appear 10–20 years after the cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent upon the status of the tissue at the time of treatment, e.g. the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful providing there is normal bone marrow to

Table 9.15 Acute oncology problems and common causes

Fever	Neutropenic sepsis
Breathlessness	Pulmonary embolus, pleural effusion Neutropenic sepsis Bronchial obstruction and lobar collapse Tense ascites
Hypotension	Neutropenic sepsis Embolus, pericardial tamponade
Swollen facies	Superior vena caval obstruction
Leg weakness	Spinal cord compression
Mental deterioration	Hypercalcaemia Raised intracranial pressure
Renal failure	Obstructive uropathy, sepsis Drugs; NSAIDs, methotrexate, cisplatin Metabolic; calcium, uric acid, myeloma protein, tumour lysis
Haemorrhage	Tumour erosion, thrombocytopenia, DIC
Bone pain	Pathological fracture
Acute abdomen	Intestinal obstruction and perforation
Jaundice	Obstructing mass, parenchymal destruction by tumour or drugs

reconstitute the haemopoietic system or the whole tissue at risk can be resected (e.g. thyroid after mantle radiotherapy for lymphoma).

ACUTE ONCOLOGY

The acute care of all patients admitted to hospital with a cancer diagnosis has become known as acute oncology, in order to ensure a coordinated patient care, with access to all facets of the multidisciplinary team and thus the most efficient use of high cost inpatient facilities. In addition, there are a number of common oncological emergencies for which urgent treatment is critical for success (Table 9.15).

Neutropenic sepsis

This is the most common cause of attendance in the emergency department for any cancer patient and must be always considered in any patient who is unwell within a month of chemotherapy. Neutropenic patients are at high risk of bacterial and fungal infection, most often from enteric bowel flora. Patients must be warned of the possibility of neutropenic fever occurring. Nonspecific symptoms are also common, e.g. nausea, diarrhoea, drowsiness, breathlessness. A fever $>37.5^{\circ}\text{C}$ may not always be present. The critical test is the full blood count and patients with neutrophils $<1.0 \times 10^9/\text{L}$ are managed by the immediate introduction of broad-spectrum antibiotics and fluid resuscitation. Treatment can be risk stratified and low-risk patients managed with oral antibiotics such as co-amoxiclav. However, signs of systemic illness such as tachycardia, hypotension, oliguria mandate urgent admission and resuscitation with intravenous treatment (Box 9.6). Initial empirical therapy should be reviewed following microbiological results. All such patients need to be discussed with the appropriate specialist oncology team and hospitals should have clear protocols for the rapid institution of antibiotics in such patients within an hour of arrival in the A&E department. In units practised in the assessment of febrile neutropenia it is possible to follow

Box 9.6 Treatment of febrile neutropenia*

- One-off reading $\geq 38.5^{\circ}\text{C}$ or a reading $\geq 38^{\circ}\text{C}$ sustained for 1 hour
- Patients on antipyretics or steroids and elderly patients may not mount a febrile response
- Hypothermia or clinical deterioration may be the first sign

Immediate intervention is essential

- Resuscitation with intravenous fluids to restore circulatory function, monitor urine output, GCS and central venous pressure
- Cultures of blood, urine, sputum and stool
- Empirical antibiotics as per local policy and sensitivities
- Intensive care review and consideration for inotropic support at an early stage
 - Commonly used antibiotics should include activity against enteric Gram-negative bacteria and *Pseudomonas*, e.g. co-amoxiclav, ceftazidime or piperacillin-tazobactam with gentamicin; meropenem monotherapy
 - May require antibiotics against staphylococci, especially with indwelling venous access lines, e.g. vancomycin
- If the patient deteriorates clinically and/or temperature still elevated after 48 hours, change antibiotics according to culture results or empirically increase Gram-negative and consider adding Gram-positive cover. Discuss with Microbiology.
- If fever not responding to broad-spectrum antibiotics
 - consider imaging, e.g. chest CT to detect occult source for fever, and adding treatment for opportunistic infections
 - liposomal amphotericin B or voriconazole – *Candida* and *Aspergillus*
 - high-dose co-trimoxazole – *Pneumocystis*
 - clarithromycin – *Mycoplasma* and *Legionella*
 - antituberculous therapy – *Mycobacterium tuberculosis*

Figure 9.11 Pulmonary embolism.

a more risk-stratified antibiotic policy and avoid or curtail admission with oral co-amoxiclav plus ciprofloxacin when low-risk features are present: i.e. absence of tachycardia, hypotension, hypoxia and mucositis and an expected short duration of myelosuppression.

Pulmonary embolus

This is a common complication of the coagulopathy of cancer and as a side-effect of chemotherapy (Fig. 9.11). It often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be kept in any cancer patient with hypoxia or chest pain. CT pulmonary angiogram

Figure 9.12 Bulky anterior mediastinal mass in a patient presenting with superior vena caval obstruction. T lymphoblastic lymphoma.

is the investigation of choice. Prophylactic anticoagulation is given to all immobilized patients (see p. 429). Warfarin is ineffective in reversing the coagulopathy of cancer and heparin is required as long as treatment continues or the cancer is active.

Superior vena caval obstruction

Superior vena caval obstruction (Fig. 9.12) can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, with stridor, swollen, oedematous facies and arms with venous congestion in the neck and dilated veins in the upper chest and arms. Treatment is with immediate steroids, vascular stents, anticoagulation and mediastinal radiotherapy or chemotherapy. Some tumours, e.g. lymphomas, small-cell lung cancers and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary on the patient's likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.

Spinal cord compression

Spinal cord compression (see p. 1135) needs to be rapidly diagnosed and urgent treatment arranged within 24 hours of onset of paresis to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective and gradual in onset. MR scanning is the investigation of choice. Treatment should begin with high-dose steroids and a joint neurosurgical and oncological consultation. Good prognosis patients with limited disease require surgical decompression and radiotherapy to the affected vertebrae to achieve the best disease control and palliation.

Tumour lysis syndrome

This occurs if treatment triggers a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate and a secondary hypocalcaemia. These biochemical changes can lead to cardiac arrhythmias and seizures. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy). Vigorous hydration, often with diuretics, is crucial to maintain high urine outputs in such patients; however, a proportion will require dialysis for uraemia, oliguria or severe electrolyte disturbances. The xanthine oxidase inhibitor allopurinol should be

given before treatment is started in low-risk patients. Intravenous rasburicase, a recombinant urate oxidase, is used for prophylaxis in high-risk patients and in the treatment of tumour lysis syndrome.

Acute hypercalcaemia

This presents with vomiting, confusion, constipation and oliguria. Treatment is by resuscitation with intravenous fluids to establish a saline diuresis and i.v. bisphosphonate, e.g. pamidronate or the more potent zoledronic acid (see Emergency Box 19.2). Treating the cause is crucial. Denosumab and calcitonin can be used in intractable cases.

Raised intracranial pressure

Raised intracranial pressure due to intracerebral metastases presents classically with headache, nausea and vomiting. There are often no localizing neurological signs and almost never papilloedema until very late in the disease. However, for many there is a slower onset with nonspecific symptoms such as drowsiness or mental deterioration. Treatment is by high-dose steroids and investigation by MRI as to whether surgery is appropriate if unifocal and/or threatening the fourth ventricle, or whole brain or local stereotactic Cyberknife radiotherapy are required.

Hyperviscosity

This can affect those with a very high haematocrit (Hb >180 g/L), white cell count (>100 × 10⁹/L) or platelet cell count (>1000 × 10⁹/L) from untreated leukaemia, or a myeloproliferative disorder. Viscosity can also be increased by high levels of monoclonal immunoglobulin molecules seen in myeloma or Waldenström's macroglobulinaemia. IgA and IgM are more commonly implicated due to their respective dimeric and pentameric structures. Clinical features include hypoxia, pulmonary infiltrates, confusion, headache, visual disturbances, papilloedema and retinal venous dilation as well as rarely cardiac failure or priapism. Treatment is by leucopheresis or plasmapheresis followed by urgent treatment for the underlying malignancy.

Malignant bile duct obstruction

This will present with cholestatic jaundice. Lymphomatous obstruction will respond very well to prompt initiation of therapy. A small proportion of pancreatic and bile duct tumours are surgically resectable, more commonly those in the distal bile duct as compared to the hilar region. However, in the greater proportion of patients the treatment is palliative. In recent years endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents which have considerably longer

periods of patency though at the risk of ascending infection. In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative. Endoscopic photodynamic laser therapy with a photoporphyrin sensitizer can also prolong patency.

HAEMATOLOGICAL MALIGNANCIES

The leukaemias, the lymphomas and multiple myeloma are an interrelated spectrum of malignancies of the myeloid and lymphoid systems. They are uncommon but not rare, the lymphomas alone being the fifth commonest cancer in the UK. The aetiology of these diseases for the most part is unknown, although viruses, irradiation, cytotoxic poisons and immune suppression have been implicated in a small proportion of cases (see p. 434). The pathogenesis involves at least one or usually more molecular abnormalities and non-random chromosomal abnormalities have been detected in several leukaemias and lymphomas. Classification has become increasingly complex, with the universally applied WHO scheme demanding morphological, cytogenetic and sometimes molecular criteria to be fulfilled. Transformation from low-grade to high-grade pathologic subtype may occur. Treatment options are multiple. Patients need to be supported through treatment involving prolonged myelosuppression and immunosuppression. These are potentially life-threatening but can also be curative. This has given rise to the need for highly skilled staff and specialist facilities; patients should be referred to these centres for treatment.

Haematological malignancies can be divided on the basis of the speed of evolution of the disease, according to the cell of origin (myeloid or lymphoid) and according to whether the presentation is primarily a marrow-based leukaemic presentation or a nodal or extranodal lymphomatous presentation where soft tissue masses predominate. This is summarized in Table 9.16. This is an arbitrary division and there is movement across the divisions, e.g. CML can transform to either AML or ALL, myeloproliferative neoplasms (MPN) and MDS can transform to AML, CLL and low-grade NHL can transform to a high-grade form 'Richter's transformation'.

The myelodysplastic syndromes are considered pre-leukaemic and are discussed on page 405. Similarly the myeloproliferative disorders may also transform to acute leukaemia and are discussed on page 402.

In the management of these diseases, it is critical that patients are apprised of the natural history, its potential modification by treatment and the risks of both severe morbidity and mortality. It must be made clear from the outset whether

Table 9.16 Classification of leukaemia and lymphoma

	Myeloid (BM)	Lymphoid (BM)	Lymphoid (Node)
Acute – rapidly progressive, fatal within days-weeks if not treated Immature cells predominate	AML	ALL	Lymphoma – 'high grade', 'aggressive', e.g. Burkitt's lymphoma
Chronic – indolent and slowly progressive and patient can live with disease for long periods Mature cells	CML Other MPD	CLL and others	Lymphoma – 'low grade', 'indolent', e.g. follicular lymphoma

ALL, acute lymphocytic leukaemia; AML, acute myeloid leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myeloid leukaemia; MDS, myelodysplastic syndrome; MPD, myeloproliferative disorder; BM, bone marrow.

^aMyeloma is a malignant disease of plasma cells.

a curative or palliative strategy is most appropriate and why. If cure is to be pursued, the patient must be apprised of the approximate probability of success and its potential price. The possibility of failure needs to be addressed at the outset.

THE LEUKAEMIAS

There are four main subtypes, as discussed above:

1. Acute myeloid leukaemia (AML)
2. Acute lymphoblastic leukaemia (ALL)
3. Chronic myeloid leukaemia (CML)
4. Chronic lymphocytic leukaemia (CLL).

These are relatively uncommon diseases with an incidence of about 10/100 000 per year, which can occur at any age. The type of leukaemia varies with age; acute lymphoblastic leukaemia (ALL) is mainly seen in childhood and chronic lymphocytic leukaemia (CLL) is a disease of the elderly.

Leukaemia can be diagnosed by examination of a stained slide of peripheral blood and bone marrow, but immunophenotyping, cytogenetics and molecular genetics are essential for complete subclassification and prognostication. The lineage and degree of maturity of the leukaemic clone can be assessed by the expression of cytosolic enzymes and expression of surface antigens.

Aetiology

In the majority of patients, this is unknown but several factors have been associated:

- **Radiation.** This can induce genetic damage to haemopoietic precursors and ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima and Nagasaki and in patients treated with ionizing radiation.
- **Chemical and drugs.** Exposure to benzene used in industry may lead to marrow damage. AML occurs after treatment with alkylating agents (e.g. melphalan) and topoisomerase II inhibitors (e.g. etoposide).
- **Genetic.** Leukaemia risk is highly elevated in a number of germline conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia telangiectasia and Li-Fraumeni syndrome. The risk is elevated some 30 times in people with trisomy 21. There is a high degree of concordance among monozygotic twins. Several genes have also been associated with familial AML such as CEBPA and RUNX1.
- **Viruses.** A type of leukaemias is associated with human T cell lymphotropic retrovirus type 1 (HTLV-1), which is found particularly in Japan and the Caribbean.

Genetic abnormalities in leukaemia

Leukaemic cells often have a somatically acquired cytogenetic abnormality, which may be of prognostic, as well as diagnostic, significance.

These genetic alterations change the normal cell regulating process by interfering with the control of normal proliferation, blocking differentiation, maintaining an unlimited capacity for self-renewal and, lastly, promoting resistance to death signals, i.e. decreased apoptosis.

The first non-random chromosomal abnormality to be described was the Philadelphia (Ph) chromosome, which is associated with CML in 97% of cases (see Fig. 9.16a). The Ph chromosome is also found in ALL, the incidence in the

latter illness increasing with age. The translocation is shown schematically in Figure 9.16a. The Ph chromosome is an abnormal chromosome 22, resulting from a reciprocal translocation between part of the long arm of chromosome 22 and chromosome 9. The resulting karyotype is described as t(9;22)(q34;q11). The molecular consequences of the translocation are that part of the Abelson proto-oncogene (c-ABL) normally present on chromosome 9 is translocated to chromosome 22, where it comes into juxtaposition with a region of chromosome 22 named the 'breakpoint cluster region' (BCR). The new 'fusion' gene BCR-ABL is capable of being expressed as a chimeric messenger RNA, which has been identified in cells from patients with CML. When translated, this produces a fusion protein that has tyrosine kinase activity and enhanced phosphorylating activity compared with the normal protein, resulting in altered cell growth, stromal attachment and apoptosis. The breakpoint differs in CML and Ph-positive ALL, leading to the production of two different tyrosine kinase proteins with molecular weights of 210 kDa and 190 kDa, respectively. It is unclear whether the presence of BCR-ABL is sufficient for the development of the disease. It has been shown that normal subjects can carry low levels of the BCR-ABL fusion gene in their blood without developing leukaemia. Other genetic and cytogenetic abnormalities are often seen in leukaemic cells (Table 9.17).

As well as cytogenetic and molecular aberrations, epigenetic modification via abnormal methylation patterns and chromatin modification due to histone acetylation is increasingly understood to be involved in oncogenesis and may represent potential therapeutic targets.

Acute leukaemias

The acute leukaemias increase in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia (AML) has a median age at presentation of 65 years and may arise *de novo* or against a background of myelodysplasia or prior cytotoxic chemotherapy ('secondary'). Acute lymphoid (lymphoblastic) leukaemia (ALL) has a substantially lower median age at presentation and in addition is the commonest malignancy in childhood. The WHO classification is shown in Table 9.17.

Clinical features

The majority of patients with acute leukaemia, regardless of subtype, present with symptoms reflecting inadequate haematopoiesis secondary to infiltration of the bone marrow by leukaemic cells, symptoms due to tissue infiltration by leukaemic cells, the consequences of a high WBC or substance release from the tumour cells (Table 9.18).

Investigations

Confirmation of diagnosis (Fig. 9.13)

- **Blood count.** Hb low, WBC raised usually (sometimes low), platelets low.
- **Blood film.** Blast cells almost invariably seen (Fig. 9.13a), lineage may be identified morphologically, e.g. presence of Auer rods is consistent with a diagnosis of AML (Box 9.7).
- **Bone marrow aspirate.** Increased cellularity, reduced erythropoiesis, reduced megakaryocytes. Replacement by blast cells >20% (often approaching 100%) (Fig. 9.13b). Lineage confirmation by immunophenotyping, e.g. AML – CD33 or CD13, B lineage ALL – CD10 and CD19 and T lineage – CD3. Cytogenetic FISH analysis in real-time PCR and molecular genetics for prognostication.

- Hyperdiploidy
- Hypodiploidy
- B-cell lymphoblastic leukaemia/lymphoma not otherwise specified
- T-cell lymphoblastic leukaemia/lymphoma

^aThe entities included in this group are defined almost identically to the corresponding entity in the French–American–British (FAB) classification.

Modified from: Jaffe ES, Harris NL, Stein H et al. (eds) *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues*. Lyon: IARC Press; 2008, with permission from the World Health Organization.

- **Chest X-ray.** Mediastinal widening often present in T lymphoblastic leukaemia.
- **Cerebrospinal fluid examination.** Performed in all patients with ALL, as the risk of CNS involvement is high. It is less critical in AML.
- Coagulation profile to exclude presence of DIC (raised PT, APTT, reduced fibrinogen, increased fibrinogen degradation products, e.g. D-dimers).

For planning therapy

- Biochemistry, serum urate, renal and liver biochemistry.
- Cardiac function; ECG and direct tests of left ventricular function, e.g. echocardiogram (see p. 685).

Principles of management

Untreated acute leukaemia is invariably fatal, most often within a few months, though with judicious palliative care, it may be extended to perhaps a year. Treatment with curative intent may be successful, or may fail, either because the

a

b

**Box 9.7 Characteristics of blast cells**

- A blast is an immature precursor of myeloid cells (myeloblasts) or lymphoid cells (lymphoblast)
- Bigger than normal counterpart
- Immature nucleus (nucleolus, open chromatin)
- Cytoplasmic appearances often atypical
- Rarely ever seen in normal individuals
- If present, are highly suggestive of an acute leukaemia or a chronic disorder that is beginning to transform into an acute disease, e.g. transformed MPN, MDS-RAEB, CML blast crisis.

leukaemia does not respond (i.e. refractory to treatment), because the disease returns after an initial favourable response (relapse) or because the patient succumbs to complications of the therapy (treatment-related mortality). At initial presentation, acute leukaemias range from being probably curable (e.g. childhood 'good risk' ALL) through to probably incurable (e.g. AML with adverse cytogenetic features in the elderly). Since curative treatment carries considerable morbidity and potential mortality, it is essential that the 'risk/benefit' ratio is clearly understood by physician and patient alike.

Palliative therapy

Every attempt should be made to ensure that the patients are at home as much as possible, while making available the full range of supportive care. Palliation may well include both low-dose chemotherapy and irradiation in addition to blood product support and antimicrobials.

Table 9.18 Symptoms and signs of leukaemia

		Symptoms	Signs	Type
Marrow failure	Anaemia	Breathlessness Fatigue Angina Claudication	Pallor Cardiac flow murmur	ALL/AML
	Neutropenia	Infections	Fever Mouth ulcers Septic focus Petechiae	
	Thrombocytopenia	Bleeding and bruising	Gum bleeding Fundal haemorrhage	
High WBC	Leucostasis	Breathlessness Headache Confusion Visual problems	Hypoxia, pulmonary infiltrates Reduced GCS Retinal vein dilation, papilloedema, fundal haemorrhage	ALL/AML
Tissue infiltration	Marrow	Bone pain		ALL/AML
	Gums		Gum hypertrophy	AML
	Skin		Violaceous skin deposits	AML
	Liver/spleen		Hepatosplenomegaly	ALL/AML
	Nodes		Lymphadenopathy	ALL/AML
	CNS	Headache	Cranial nerve palsies	ALL/(AML)
	Testes		Testicular enlargement	ALL
	Mediastinum		Mediastinal mass, SVC/O	ALL
Substance release	DIC	Bleeding and bruising	Ecchymoses Bleeding i.v. sites	AML
	Hyperuricaemia	Acute gout Tumour lysis	Renal stones, tophi Acute kidney failure	ALL/AML

GCS, Glasgow Coma Score; SVC/O, superior vena caval obstruction; DIC, disseminated intravascular coagulopathy.

Curative therapy

The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year. In the short term, it may demand transfer to another hospital, as acute leukaemia should only be treated in units seeing at least 10 such cases per year. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days' to weeks' duration, requiring discussions and decisions about work or education.

The decision to treat with curative intent implies that cure is possible and that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected. The failure rate may be high and the patient must know that he or she will be told if cure becomes an unrealistic goal.

Active therapy

Supportive care

This forms the basis of treatment whether for cure or palliation:

- Avoidance of symptoms of anaemia (haemoglobin >80–100 g/L) – repeated transfusion of packed red cells (sometimes irradiation of cells is required)
- Prevention or control of bleeding (platelet count <10×10⁹/L in the stable and <20×10⁹/L in the septic patient or <50 if a procedure is planned, e.g. a lumbar puncture). Coagulation abnormalities should be corrected with FFP to keep APTR/INR <1.5×normal and with cryoprecipitate to keep the fibrinogen level >1.5 g/dL. Norethisterone is given to women of menstrual age to avoid menorrhagia during their thrombocytopenic phase.

Leucopheresis may be required to reduce the white cell count rapidly before the chemotherapy has started to be effective.

- Treatment of infection (see Box 9.6):

- **Prophylactically.** Education of patients, relatives and staff about hand washing and isolation facilities. Selected antibiotics, antifungals, antivirals and *Pneumocystis jiroveci* prophylaxis may be required.
- **Therapeutically.** Management of fever with protocol/algorithm of antibiotic and antifungal combinations.

- Control of hyperuricaemia with hydration, prophylactic allopurinol and occasionally rasburicase (see p. 479).

Indwelling venous devices, e.g. Hickman line, are required to allow easy access to the blood for tests and administration of therapy. Sperm banking is offered to postpubertal men and oocyte collection to women, if there is time before treatment.

Specific treatment

The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission; CR). This 'induction chemotherapy' is tailored to the particular leukaemia and the individual patient's risk factors. Since this treatment is not leukaemia specific but also impairs normal bone marrow function, it leads to a major risk of life-threatening infection, which increases the risk of early death in the short term.

Successful remission induction is always followed by further treatment (consolidation). The details of this are determined by the type of leukaemia, the patient's risk factors and the patient's tolerance of treatment. Recurrence is almost invariable if 'consolidation' therapy is not given. This reflects the lack of sensitivity of the definition of 'complete remission', which has been solely morphological. Cytogenetics and molecular genetic techniques can however identify residual leukaemic cells not detected morphologically and they are highly predictive of recurrence. Recommendations have recently been made to modify the definition of remission to reflect this. Failure to achieve morphological CR with two cycles of therapy ('refractory') carries almost as bad a

prognosis as the untreated leukaemia. If CR can be achieved, e.g. by new experimental approaches, cure may still be possible with stem cell transplantation (see p. 444). A small proportion of patients with refractory disease may also be cured by a myeloablative allograft.

Acute myeloid leukaemia (AML)

In AML, the prognosis is dependent on a range of key variables, the two main ones being age and cytogenetics (Fig. 9.14; Table 9.19).

Treatment with curative intent is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Treatment success reflects the cytogenetic pattern. Those at 'low risk' are treated with moderately intensive combination chemotherapy. This always includes an anthracycline such as daunorubicin and cytosine arabinoside (cytarabine) and consolidation with a minimum of four cycles of treatment given at 3–4-week intervals. Patients with low-risk disease do not benefit from allogeneic stem cell transplantation during their first complete remission because the risks outweigh benefits. Those at 'intermediate risk' are a heterogeneous group. When possible, they should

Figure 9.14 Prognosis related to cytogenetics and molecular data in AML Outcome of younger adults with AML treated in the MRC AML10 and AML12 trials stratified according to cytogenetic and molecular abnormalities.

Table 9.19 AML risk factors

Good risk	Poor risk
De novo disease	Age >60
Favourable cytogenetics t(15;17) t(8;21) or inv(16) or its variant t(16;16)	Male
CEBPA biallelic mutation	Secondary disease, e.g. prior MDS or MPN
NPM1 mutation with FLT3 wild type	High WBC
	Adverse cytogenetics: -5, del(5q), -7, abnormal 3q26 or a complex karyotype
	FLT3 internal tandem duplication mutation
	MRD positivity

be given consolidation chemotherapy after an initial remission has been achieved followed by allogeneic transplantation only in those who are deemed at increased risk of relapse because of other risk factors, e.g. mutational data. Patients with high-risk disease should proceed to a stem cell transplant in CR1 because they respond poorly to conventional chemotherapy and have a high risk of relapse.

Complete remission (CR) will be achieved in about 80% of patients under the age of 60. Failure is due to either resistant leukaemia (10%) or death due to infection or bleeding (10%). Approximately 50% of those entering complete remission will be cured (i.e. approximately 40% overall) although this varies from 60–70% in the favourable cytogenetic group to 10–20% in the adverse cytogenetic group.

The initial treatment of the older patient is much more contentious. Older patients tolerate cytotoxic therapy less well than younger patients due to co-morbidities and their disease is often more aggressive in its biology, e.g. adverse cytogenetics are more common with increasing age. Reduced intensity allogeneic transplantation is increasingly being used for this group but is limited by the toxicity of this treatment.

The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor despite the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. Experimental therapy should be considered. The use of minimal residual disease monitoring may allow the detection of a subgroup of patients during initial therapy who require treatment intensification, e.g. allograft, as well as patients in CR who are at the early stages of relapse and need preemptive therapy before frank marrow relapse occurs.

Newer agents that target the FLT3 mutation, present in a significant proportion of cases of AML, are in clinical trials in conjunction with conventional chemotherapy. Other novel therapies that are being considered in AML include chemotherapy labelled monoclonal antibodies (gemtuzumab ozogamicin) and hypomethylating agents (azacitidine).

Acute promyelocytic leukaemia (APML)

This is a variant of AML, occurring in 10–15% of cases, that is characterized by the translocation t(15;17) and with particular morphological features. There is an almost invariable coagulopathy, which was a major cause of early death. The empirical discovery that all-trans-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. APML is treated with ATRA combined with several courses of chemotherapy. Complete remission and molecular remission occur in at least 90% of younger adults with APML and at least 70% will expect to be cured. Transplantation may be necessary either if the leukaemia is not eliminated at the molecular level, or following recurrence and reinduction therapy. Arsenic trioxide, which induces apoptosis via activation of the *caspase cascade* (see p. 33), is used with resistant or relapsed disease and is under investigation as first-line therapy.

Acute lymphoblastic leukaemia (ALL)

This condition may present in leukaemic phase with significant marrow involvement (ALL) or may present as localized disease, typically a mediastinal mass (lymphoblastic lymphoma). The tumour cells in each condition are indistinguishable and similar therapies are therefore used. The overall strategy for the treatment of ALL differs in detail from that for AML. Remission induction is undertaken with combination chemotherapy including vincristine, a glucocorticoid, an

anthracycline and asparaginase. Once remission is achieved, the details of consolidation will be determined by the anticipated risk of failure. Intensive consolidation of remission with variable numbers of chemotherapy cycles comprising cytotoxics with different mechanisms of action has been standard practice, including the administration of high-dose methotrexate. In those patients with high-risk features (see below) or an HLA-matched sibling donor, allogeneic transplantation is recommended upon achieving first complete remission (CR1).

A major difference between therapy for ALL and AML is the need for central nervous system directed therapy. Prophylaxis should be given with intrathecal chemotherapy under platelet cover if necessary, as soon as blasts are cleared from the blood. Depending upon risk this may be continued for up to 2 years and complemented by high doses of systemic cytosine arabinoside (cytarabine) or methotrexate. Cranial irradiation was previously given to all patients to reduce the risk of relapse within the central nervous system; some risk adapted strategies reserve this only for those patients at very high risk.

Additionally, after intensive induction and consolidation, maintenance therapy for 2 years is required to reduce the risk of disease recurrence. This typically comprises 2 years of treatment with methotrexate and mercaptopurine, although more intensive regimens are used by many groups.

Prognostic factors

A number of clinical and laboratory features are determinants of treatment response and survival in ALL (Table 9.20). Increasingly, therapeutic strategies based upon prognostic risk are being used in the management of the disease.

Prognosis

The prognosis (Fig. 9.15) of ALL in childhood is now excellent: complete remission is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high presentation blast counts or a t(9;22) translocation. Current treatment strategies are to lessen therapy for 'good risk' children in order to avoid some of the long-term consequences of therapy such as avascular necrosis of bone, infertility, neurotoxicity and cardiotoxicity.

The situation is far less satisfactory for adults, the prognosis getting worse with advancing years. Co-morbidity and t(9;22) translocation increases in frequency with age. Overall, the complete remission rate is 70–80%. Disease that is refractory to first-line therapy carries a very poor prognosis. Between 30% and 40% of patients continue in durable first remissions, resulting in approximately 25–30% overall patient cure. Increasing numbers of patients are being transplanted for this condition, including those with sibling donors and those high-risk patients with an available unrelated donor. Imatinib used in conjunction with chemotherapy increases the response rate and quality of response in patients with the

t(9;22) translocation and ALL. As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured.

Chronic leukaemias

Chronic myeloid leukaemia (CML)

Chronic myeloid leukaemia (CML), which accounts for about 14% of all leukaemias, is one of the family of myeloproliferative neoplasms (MPNs) and is almost exclusively a disease of adults with the peak of presentation being between 40 and 60 years. It is defined by the presence of the Philadelphia chromosome (Fig. 9.16), either demonstrated cytogenetically (95%) or molecularly (5%). Unlike the acute leukaemias which are either rapidly reversed or rapidly fatal, CML has a more slowly progressive course, which if not initially cured, will be followed eventually by 'blast crisis' transformation to acute leukaemia (75% myeloid, 25% lymphoid) or myelofibrosis with death in a median of 3–4 years.

Clinical features

CML usually presents in the chronic phase and some patients have no symptoms. *Symptoms* will include:

- Symptomatic anaemia (e.g. shortness of breath)
- Abdominal discomfort due to splenomegaly
- Weight loss
- Fever, sweats, in the absence of infection
- Headache (occasionally) or priapism due to hyperleucocytosis
- Bruising, bleeding (uncommon)

Table 9.20 Acute lymphoblastic leukaemia (ALL) risk factors

Risk factor	Good	Poor
Age	Younger age	Older age
WBC	$<50 \times 10^9/L$ for B-lineage $<100 \times 10^9/L$ for T-lineage	$>50 \times 10^9/L$ for B-lineage $>100 \times 10^9/L$ for T-lineage
Immunophenotype	CD10 + common ALL	Pro-B ALL
Cytogenetic aberrations	t(12;21) hyperdiploidy	t(9;22) or t(4;11) hypodiploidy
Time to response	Early clearance of blasts	Failure to achieve a CR within 3–4 weeks
Minimal residual disease	MRD negative	MRD positive
Extramedullary disease	CSF clear	CSF positive

Figure 9.16 The Philadelphia chromosome (Ph). (a) The long arm (q) of chromosome 22 has been shortened by the reciprocal translocation with chromosome 9. (b) The Philadelphia chromosome is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

Signs will include:

- Pallor
- Splenomegaly, often massive
- Lymphadenopathy (uncommon, suggests blast crisis)
- Extramedullary soft tissue leukaemic deposit 'chloroma' (= blast crisis)
- Retinal haemorrhage due to leucostasis.

Investigations

- **Blood count.** Hb low (normochromic and normocytic) or normal, WBC raised (usually $>100 \times 10^9/L$), platelets low, normal or raised.
- **Blood film.** Neutrophilia with the whole spectrum of mature myeloid precursors. Elevated basophils and eosinophils. Increased numbers of blasts are suggestive of accelerated phase or blast crisis.

Blood film showing blast cells in CML.

- **Bone marrow aspirate.** Increased cellularity, increased myeloid precursors. Cytogenetics reveals t(9; 22) translocation (the Philadelphia chromosome) (Fig. 9.16b).
- **Fluorescence in situ hybridization (FISH)** or reverse transcriptase polymerase chain reaction (RT-PCR) are used to demonstrate the cytogenetic/molecular abnormality. These are also used to quantitatively monitor response to therapy.

Management

Treatment has been transformed by the advent of imatinib, a tyrosine kinase inhibitor that specifically blocks the enzymatic action of the BCR-ABL fusion protein, which is now first-line treatment for the chronic phase. Imatinib produces a complete haematological response in over 95% of patients and 70–80% of these have no cytogenetically detectable BCR-ABL translocation in the marrow (complete cytogenetic remission). A proportion will lose molecularly detectable BCR/ABL transcripts from the blood (complete molecular remission). Event-free and overall survival appear to be better than for other treatments. Side-effects of imatinib include nausea, headache, rashes and cytopenia. Imatinib can be continued indefinitely although it should be stopped before attempting to conceive. Resistance to imatinib as a single agent may develop as a result of secondary BCR/ABL kinase mutations beyond the t(9;22). The use of second-generation tyrosine kinase inhibitors, dasatinib and nilotinib, may restore haematological or molecular remissions in those patients in the chronic phase that have primary or acquired resistance to imatinib or who are intolerant to imatinib. Both dasatinib and nilotinib have demonstrated promise in the first-line setting although it remains to be seen whether any advantage over imatinib in speed or depth of response is sustained over time. Bosutinib and ponatinib are also under evaluation.

In the acute phase (blast transformation) most patients have only a short-lived response to imatinib and other chemotherapy, as for acute leukaemia, and stem cell transplantation is used in the hope of achieving a durable remission.

Stem cell transplantation (SCT)

Allogeneic haemopoietic stem cell transplantation can cure approximately 70% of chronic phase CML patients. It is now used in those with an inadequate response to imatinib or those that have disease progression on therapy.

Chronic lymphocytic leukaemia (CLL)

This is the most common leukaemia, occurring predominantly in later life and increasing in frequency with advancing years (median age of presentation between 65 and 67 years). It results from the clonal expansion of small lymphocytes and is almost invariably (95%) B cell in origin. The majority of patients are asymptomatic, identified as a chance finding on a blood count performed for another indication. Other patients, however, present with the features of marrow failure or immunosuppression. The median survival is about 10 years and prognosis correlates with clinical stage at presentation (Table 9.21). A number of cytogenetic and molecular abnormalities are now recognized as being of prognostic significance (see below). This condition may present in leukaemic phase with significant marrow involvement (CLL) or may present as localized disease (small lymphocytic lymphoma, SLL). The tumour cells in each condition are indistinguishable and a similar therapeutic approach is therefore used. A pre-malignant condition, monoclonal B cell lymphocytosis (MBL) exists where there are less than the $5 \times 10^9/L$ B-cells required for a diagnosis of CLL. Some of these have CLL phenotype and may progress to CLL.

Table 9.21 The Rai and Binet staging systems for chronic lymphocytic leukaemia^a

System and stage	Risk	Manifestations	Patients (%)	Median survival (years)	Recommended treatment
Rai staging system					
0	Low	Lymphocytosis	31	>10	Watch and wait
I	Intermediate	Lymphadenopathy	35	9	Treat only with progression ^b
II	Intermediate	Splenomegaly, lymphadenopathy, or both	26	7	Treat only with progression ^b
III	High	Anaemia, organomegaly	6	5	Treatment indicated in most cases
IV	High	One or more of the following: anaemia, thrombocytopenia and organomegaly	2	5	Treatment indicated in most cases
Binet staging system					
A	Low	Lymphocytosis, <3 lymphoid areas enlarged ^c	63 ^d	>10	Watch and wait
B	Intermediate	≥3 Lymphoid areas enlarged ^c	30	7	Treatment indicated in most cases
C	High	Anaemia, thrombocytopenia or both	7	5	Treatment indicated in most cases

^aLymphocytosis is present in all stages of the disease.
^bProgression is defined by weight loss, fatigue, fever, massive organomegaly and a rapidly increasing lymphocyte count.
^cLymphoid areas include the cervical, axillary and inguinal lymph nodes, the spleen or the liver.
^dStage A includes all patients with Rai stage 0 disease, two-thirds of patients with Rai stage I disease and one-third of those with Rai stage II.
 From Dighiero G, Binet JL 2000. When and how to treat chronic lymphocytic leukaemia. *New England Journal of Medicine* 343:1800, with permission.

Clinical features

The majority of patients are asymptomatic at presentation. Common symptoms will be:

- Recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- Anaemia due to haemolysis or marrow infiltration
- Painless lymphadenopathy
- Left upper quadrant discomfort (from splenomegaly).

The commonest findings on examination will be:

- Anaemia
 - Fever (due to infection)
 - Lymphadenopathy (may involve single area or be generalized)
 - Hepatosplenomegaly, sometimes massive
- However, none of these may be present.

Investigations

- **Blood count.** Hb normal or low; WBC raised and may be very high; with lymphocytosis (criteria for diagnosis $>5 \times 10^9/L$), platelets normal or low.
- **Blood film.** Small or medium sized mature and normal appearing lymphocytes. May see smudge cells *in vitro*. No immature blasts are evident.
- **Bone marrow.** Reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- **Immunophenotyping** shows mainly CD19+, CD5+, CD23+ B cells with weak expression of CD20, CD79b and surface immunoglobulin (kappa and lambda light chains).
- **Cytogenetics/FISH analyses** are not essential for diagnosis but help in the assessment of prognosis.
- **Direct Coombs' test.** May be positive if there is haemolysis.
- **Immunoglobulins.** Low or normal.

Prognostic biomarkers

The clinical course of CLL is variable. Several markers are used to supplement clinical stage and have been shown

to predict progression and survival. Variations in predictor cut-off levels have limited their widespread application.

Cytogenetic abnormalities are detected in >90% of cases. Patients with an isolated deletion of 13q have an excellent prognosis, in contrast to those with either 11q deletion or 17p deletion (the sites of the tumour suppressor genes ATM and TP53, respectively) who tend to have a rapidly evolving clinical course. In those tumours that demonstrate a high level of mutation within the variable region of the rearranged immunoglobulin heavy chain (IgVH), the clinical course is more indolent than those where the IgVH sequence more closely resembles that of the germline. Expression of ZAP70, a 70 kDa tyrosine kinase protein, correlates well with mutational status. Patients with <20% expression of ZAP70 have median 10-year survival of >50%; in >20% expression the median survival was <5 years. High expression of CD38 on leukaemic cells may also indicate adverse prognosis.

Management

In CLL, the major consideration is when to treat, indeed 30% of patients will never require intervention. Treatment depends on the 'stage' (Table 9.21) of the disease. Choice of therapy will depend upon patient-related factors such as age and co-morbidity, adverse prognostic features and anticipated response and toxicities to therapy. Intervention, when indicated, usually causes improvement in symptoms and in the blood count. The effect on survival is unclear.

Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately and the approach to the intermediate stage is variable. The absolute indications for treatments are:

- Marrow failure manifest by worsening anaemia and/or thrombocytopenia
- Recurrent infection
- Massive or progressive splenomegaly or lymphadenopathy
- Progressive disease manifest by doubling of the lymphocyte count in 6 months
- Systemic symptoms (fever, night sweats or weight loss)

- Presence of haemolysis or other immune-mediated cytopenias.

General/supportive treatment

Anaemia due to haemolysis is treated with steroids. Anaemia and thrombocytopenia due to marrow infiltration is treated with chemotherapy and, when necessary, transfusion. Erythropoietin (see p. 374) may avoid the need for transfusions, particularly in patients receiving chemotherapy.

Infection is treated as indicated, with prophylactic antibiotic, antiviral, anti-PCP therapy and antifungal therapy potentially being given during periods of chemotherapy. Immunoglobulin replacement may be helpful.

Allopurinol is given to prevent hyperuricaemia.

Specific treatment

- Chlorambucil usually reduces the white cell count and decreases lymphadenopathy and splenomegaly and successfully palliates the disease. In asymptomatic patients without an indication for therapy, early use of chlorambucil does not provide a survival advantage over expectant management.
- Combination therapy with rituximab shows a dramatic improvement in the response rate and has become standard of care as first-line therapy – FCR (fludarabine, cyclophosphamide, rituximab).
- Purine analogues, fludarabine alone or in combination with cyclophosphamide or mitoxantrone (with or without steroids), have had a much greater impact on the bone marrow and can induce complete or molecular complete remission although they are not helpful in patients with 17p deletion or TP53 mutation.
- Alemtuzumab, a humanized monoclonal antibody targeting CD52 which is highly expressed on B-CLL, is used in those patients that progress after fludarabine or who have 17p deletion or TP53 mutation
- Ofatumumab is a new generation anti-CD20 monoclonal antibody that binds to a different epitope to that of rituximab and is used for treatment of fludarabine or alemtuzumab refractory CLL
- Allogeneic stem cell transplantation with non-myeloablative conditioning regimens is increasingly performed.

Lymphomatous transformation

CLL may undergo lymphomatous (Richter's) transformation in 5–10% of cases, most typically to diffuse large B-cell lymphoma, although Hodgkin's like transformation is recognized. In the main, response to cytotoxic chemotherapy is unsatisfactory and survival short.

Hairy cell leukaemia (HCL)

HCL is a clonal proliferation of abnormal B (or very rarely T) cells which, as in CLL, accumulate in the bone marrow and spleen. It is a rare disease, median age at presentation is 52 years old and the male to female ratio is 4:1. The bizarre name relates to the appearance of the cells on a blood film and in the bone marrow – they have an irregular outline owing to the presence of filament-like cytoplasmic projections.

Clinical features

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80%, lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

Treatment

The purine analogues 2-chloroadenosine acetate (2-CDA; cladribine) and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions can last for many years and patients can be successfully retreated. Rituximab is used in cases who do not respond to the above drugs.

THE LYMPHOMAS

The lymphomas are malignancies of the lymphoid system and hence may arise at any site where lymphoid tissue is present. Certain subtypes have increased in frequency over the past 50 years for reasons which are not clear, the overall incidence being 15–20 per 100 000 population making them the fifth most common malignancy in the Western world. Most commonly patients have peripheral lymphadenopathy or symptoms due to occult lymph nodes, although approximately 20% arise at primary extra-nodal sites. A relatively small proportion present with lymphoma-associated 'B' symptoms of weight loss, fever and sweats. The natural history and clinical course are determined by the pathological subtype, classified by histological, immunological and molecular criteria, the distribution of the disease ('Stage'), nonspecific prognostic features and general co-morbidity.

A significant proportion of patients are cured and many others are helped both in terms of quality and length of life.

The WHO classification of Tumours of Haematopoietic and Lymphoid Tissues primarily distinguishes Hodgkin's lymphoma from non-Hodgkin's lymphoma, an umbrella term covering a multiply subclassified spectrum of B- and T-cell malignancies, reflecting the stage of lymphoid development at which they arise. Thus, lymphoblastic lymphoma and lymphoblastic leukaemia are considered as a single entity, as are small lymphocytic lymphoma and chronic lymphatic leukaemia, both discussed in the section above.

Overall management strategy common to all lymphomas

A suspected diagnosis of lymphoma should always be confirmed by an excision biopsy of the relevant tissue large enough to allow histological, immunological and molecular analysis. Cutting needle biopsy is an acceptable substitute for biopsy of impalpable, 'occult' disease, but fine needle aspiration is inadequate. The opinion of an expert haematopathologist is essential.

Investigation

The diagnosis having been established, the treatment strategy and details will depend on the outcome of investigations that are common to all the lymphomas. These investigations are conducted to provide a basis for prognostication and treatment decisions, against which the outcome of treatment may be assessed (Table 9.22), 'stage' being assigned notionally to the modification of the Ann Arbor classification for all nodal lymphomas despite the fact it was planned only for Hodgkin's disease.

The tests in Table 9.22 are essential for planning specific therapy. The serum uric acid is helpful, particularly in those lymphomas in which there is risk of tumour lysis syndrome (see p. 449), tests of cardiac function when potentially cardiotoxic chemotherapy is to be recommended, as well as HIV, hepatitis B and C status.

Upon completion of these investigations, within a maximum of 2 weeks, a treatment plan should be presented to the

	Castleman's disease

patient. Central to this is the expectation of success and whether treatment is given with curative or palliative intent. The options will range from expectant management to immediate intervention with intensive therapy, itself potentially life-threatening. A decision to 'treat' having been made, a course of treatment will begin, during which benefit will be assessed at appropriate intervals and subsequent to which complete re-evaluation ('re-staging') will be performed. Depending on the outcome, future plans will be made. In the event of a decision to stop treatment, surveillance will in the first instance, be close, the interval between attendances being extended with the passage of time. Beyond 5 years, the focus of attention is upon the possible long-term consequences of therapy, rather than the disease itself. For those for whom the initial therapy has been less successful than wished, management will be dictated by individual circumstances. As conventional treatment becomes exhausted, experimental therapy may be broached.

Hodgkin's lymphoma (HL)

HL occurs with an incidence of approximately 3 per 100 000 in the Western world; there is a male predominance of approximately 1.3:1. The majority of cases occur between the ages of 16 and 65, with a peak in the 3rd decade. The incidence is stable.

Aetiology

There is epidemiological evidence linking previous infectious mononucleosis with HL; up to 40% of patients with HL have increased EBV antibody titres at the time of diagnosis and EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected. Other environmental and occupational exposures to pathogens have been postulated.

Diagnosis

Hodgkin's lymphoma is subclassified according to the WHO classification (Table 9.23) into:

1. **Classical Hodgkin's lymphoma (cHL)**, the hallmark of which is the Reed–Sternberg cell (Fig. 9.17), accounting for 90–95% of cases and which is further subdivided into four distinct categories
2. **Nodular lymphocyte predominant HL (NLPHL)**, characterized by the Reed–Sternberg cell variant, the 'popcorn cell'.

Figure 9.17 Histological appearance of Hodgkin's lymphoma. Scattered mononuclear Hodgkin's cells and a classical malignant binucleate Reed–Sternberg cell (arrow) are seen to the right of centre on a background of benign small lymphocytes and histiocytes. (Courtesy of Dr AJ Norton.)

Clinical features

The commonest presentation of HL is painless cervical lymphadenopathy, commonly described in examination as 'rubbery'. Other causes of cervical lymphadenopathy are shown in Table 9.24. A smaller proportion present with disease localized to the mediastinum (often young women), with cough due to mediastinal lymphadenopathy

(Fig. 9.18), others with 'generalized disease', including hepatosplenomegaly and constitutional 'B' symptoms. Other less common symptoms, undoubtedly associated with Hodgkin's lymphoma, but not recognized in the staging classification, are pruritus and alcohol-related pain at the site of lymphadenopathy.

Investigation

This is summarized in Table 9.22. Bone marrow biopsy is only indicated in patients with clinically advanced disease (stage III, IV), those with 'B' symptoms and those who are HIV-positive. The clinical utility of the PET scan is becoming established in the management of Hodgkin's lymphoma (Fig. 9.19).

'Stage' is currently assigned according to the Cotswolds modification of the Ann Arbor Classification, although this is under review (Table 9.25). The Hasenclever score is used for

prognostication (Box 9.8); however its relevance to treatment planning is limited because of the very small number of patients at high risk of standard treatment failure. On the basis of 'stage' and other prognostic factors, patients with HL are divided into three groups (Table 9.26).

Initial management

Treatment is aimed towards a curative intent with expectation of success. However, in patients with NLP HL who usually present with stage I disease with longstanding lymphadenopathy, an expectant policy with close surveillance, is followed. Older patients, with or without co-morbidity,

Figure 9.18 Chest X-ray of a mediastinal mass that is due to Hodgkin's lymphoma.

Table 9.25 Cotswolds modification of Ann Arbor staging classification of Hodgkin's lymphoma

Stage	Description
Stage I	Involvement of a single lymph-node region or lymphoid structure (e.g. spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site
Stage II	Involvement of two or more lymph-node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph-node region(s) on the same side of the diaphragm (IIIE). The number of anatomic regions involved should be indicated by a subscript (e.g. II ₃)
Stage III	Involvement of lymph-node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (IIIS) or by localized involvement of only one extranodal organ site (IIIE) or both (IIISE)
III1	With or without involvement of splenic, hilar, coeliac or portal nodes
III2	With involvement of para-aortic, iliac and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph-node involvement
Designations applicable to any disease state	
A	No symptoms
B	Fever (temperature >38°C), drenching night sweats, unexplained loss of >10% of body weight within the previous 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third of the presence of a nodal mass with a maximal dimension >10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

Early favourable	Stage I + II without unfavourable prognostic factors
Early unfavourable	Stage I + II with unfavourable factors
Advanced	The remainder

require considerable modification of therapy and there is an expectation of success. Patients with HIV infection should be managed, in conjunction with their HIV clinicians, in the same way as those who are seronegative.

Treatment

Early stage, 'low risk'

'Moderate' chemotherapy, comprising 2–4 cycles of doxorubicin, bleomycin, vinblastine and dacarbazine (ABVD), non-sterilizing and of a low second cancer risk, followed by involved field irradiation (20–30 Gy) has replaced large field irradiation (p. 435), with 90% being cured. Current trials are evaluating the role of PET scanning to see if patients who become 'PET' negative' after chemotherapy can be spared irradiation altogether.

Advanced disease (including locally advanced unfavourable early stage)

This is also curable for a significant proportion of patients with a median survival well exceeding 5 years for 50–60% of patients. Cyclical chemotherapy with 6–8 cycles of ABVD with involved field irradiation to sites which were initially bulky, or at which there is 'persistent disease' after chemotherapy, is standard. Increasingly, the data from studies incorporating PET scanning both part way through and after planned chemotherapy have shown that PET–ve masses are likely to represent fibrous tissue and that in this situation irradiation may be omitted.

The major short-term toxicity relates to myelosuppression and mucositis, the mortality being no more than 1% and the long-term risks being to the heart and lungs. Infertility and second malignancy are uncommon.

The above approach fails for about 25% of patients. More intensive treatment programmes, e.g. BEACOPP with additional etoposide (E) procarbazine (P) and prednisolone (P), have been tested with an overall increase in efficacy, but with greater toxicity profiles (and expense). It remains a challenge to identify those who will be 'ABVD failures' at initial presentation. An alternative is to develop 'risk-adapted' therapy, based on the response to the first two cycles of therapy, again with PET scanning and escalate to more intensive therapy in those in whom the response is deemed inadequate.

Management of failure of initial therapy

This has become a declining problem because of improvements in the outcome of first-line therapy. The median survival from first recurrence is more than 10 years, possibly being influenced by the duration of the first remission; it may not be so good if failure occurs after very intensive therapy. Second and third remissions may be achieved with 'appropriate' re-induction therapy, consolidated, if possible with an autograft. Registry data suggest this may be curative for up to 50%, but follow-up only extends to 15 years.

Experimental approaches

With such excellent results of first- and second-line conventional therapy, experimental treatment is seldom required. The antigen-targeted immunoconjugate, anti-CD-30-austatin (SGN-35, brentuximab) has shown such efficacy in phase II trials and the histone deacetylase inhibitor (HDAC) panobinostat also has potential. Allogeneic haemopoietic stem cell transplantation (HSCT) following myeloablative conditioning has high treatment-related mortality and morbidity. Reduced intensity conditioning HSCT, followed if necessary by donor lymphocyte infusion, is being investigated.

Long-term follow-up

The risks of late effects of therapy, particularly second malignancy and cardiac and endocrine problems, require appropriate and indefinite surveillance of patients at 'high risk'.

Non-Hodgkin's lymphomas (NHL)

Defined by the WHO classification (Table 9.27), approximately 80% of NHL are of B-cell origin and 20% of T-cell origin, there being considerable geographical variation. The incidence has increased, not necessarily for all subtypes, from 5 to 15 per 100 000 per year in the last half century.

Aetiology

A family history is associated with a minor increase in risk of lymphoma and common genetic polymorphisms with only a small risk for an individual may be significant in population

 Modified from: Jaffe ES, Harris NL, Stein H et al. (eds) *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues*. Lyon: IARC Press; 2008, with permission from the World Health Organization.

terms. Certain inherited syndromes, e.g. ataxia-telangiectasia and Wiskott-Aldrich syndrome, are associated with an increased risk of lymphoma. The human T-cell leukaemia virus type 1 (HTLV-1) is causally related to adult T-cell lymphoma/leukaemia. *Helicobacter pylori* is known to 'cause' extranodal marginal zone lymphoma in the stomach. There is a very strong epidemiological relationship between EBV and endemic Burkitt's lymphoma and a lesser one with sporadic Burkitt's lymphoma and Hodgkin's lymphoma.

Immune suppression, immunosuppressant drugs, particularly as used for solid organ transplantation, and HIV infection are all associated with an increased incidence of lymphoma. Agricultural work is associated with lymphoma, but no other data show any convincing evidence of an association between occupation or lifestyle. In the majority of individual cases, the cause is unknown.

Pathogenesis

Malignant clonal expansion of lymphocytes occurs at different stages of lymphocyte development, leading to the different subtypes of lymphoma (Fig. 9.20). In general, neoplasms of non-dividing mature lymphocytes are 'indolent', whereas those of proliferating cells (e.g. lymphoblastic) are much more 'aggressive'. Malignant transformation is usually due to errors in gene rearrangements which occur during the class switch, or gene recombinations for immunoglobulin and T-cell receptors. Thus, many of the errors occur within immunoglobulin loci or T-cell receptor loci. For example, an

abnormal gene translocation may lead to the activation of a proto-oncogene, by moving it next to a promoter sequence for the immunoglobulin heavy chains (Ig-H).

Cytogenetic features

Burkitt's lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene (Table 9.28). The most frequent change is a translocation between chromosomes 8 and 14 in which the MYC oncogene is translocated from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene on chromosome 14, resulting in upregulation of myc. Similar rearrangements involving the light chain loci are seen in the alternative Burkitt's lymphoma translocations between chromosome 8 and either chromosome 2 or 22. Other somatic cytogenetic abnormalities associated with human lymphoma are the t(14;18) in follicular lymphoma, involving upregulation of BCL2 or the upregulation of the cell cycle regulator cyclin D1, as a result of t(11;14) in mantle cell lymphoma. Gene expression profiling and other molecular techniques are identifying new molecular subclasses of lymphoma with prognostic significance.

Diagnosis

The non-Hodgkin's lymphomas are subclassified according to the cell of origin (T or B lineage) and the stage of lymphocytic maturation at which they develop (precursor or mature) (see above).

Figure 9.20 Differentiation of T and B lymphocytes and their relationship to neoplasms. Top. T-cell differentiation.

Progenitor T cells from the bone marrow enter the thymus and develop into different naive T cells. $\alpha\beta$ T cells leave the thymus, are exposed to antigen (AG) and undergo blast transformation. They then develop into CD4+ and CD8+ effector and memory T cells. T regulatory cells are the major type of CD4+ effector cells. The other specific effector T cells are the follicular helper T cell (TFH) in the germinal centres (GC). Upon antigenic stimulation, T-cell responses to antigenic stimulation pathways of natural killer cells (NK) and $\gamma\delta$ T cells is unknown.

Bottom. B cell differentiation. Precursor B cells mature in the bone marrow and undergo apoptosis or mature to naive B cells. Following exposure to antigen and blast transformation, they develop into short-lived plasma cells or enter the germinal centre (GC). Somatic hypermutation and heavy chain class switching occur here (not shown). The transformed cells of the GC (centroblasts) undergo apoptosis or develop into centrocetes. Post-GC cells include long-lived plasma cells and memory/marginal cells. AG, antigen; DLBCL, diffuse large B-cell lymphoma; CLL/SLL, chronic lymphocytic leukaemia/small lymphocytic lymphoma. Clinical presentation

The commonest presentation overall is with painless lymphadenopathy or with symptoms caused by a lymph node mass. Primary extranodal lymphomas present with soft tissue masses and related symptoms at the relevant site.

Specific non-Hodgkin's lymphomas

The more common subtypes of non-Hodgkin's lymphomas are described below.

B-cell lymphomas (Fig. 9.21)

Follicular lymphoma

This is the second commonest non-Hodgkin's lymphoma (comprising approximately 20% of the lymphomas in the world).

Clinical presentation and course

Follicular lymphoma occurs in middle to late life, being rare in childhood. The majority of patients will present with painless lymphadenopathy at more than one site, although a small proportion will be ill, some with 'B' symptoms. In the latter, there should be suspicion that the diagnostic biopsy was not representative. This may be the case when the presenting symptom relates to an abdominal mass, but a peripheral node is biopsied. Percutaneous needle biopsy of the abdominal mass may reveal transformation to diffuse large B-cell lymphoma, with potentially different management. Bone marrow infiltration is common in certain subtypes.

There have been dramatic improvements in the outcome of therapy since the introduction of antibody therapy (rituximab), targeting the CD20 antigen expressed on almost all B-cell lymphomas, leading to the development of chemoimmunotherapy, but to date, however, the proportion of patients cured has been small. The illness has been shown to regress spontaneously in some cases which has led to an expectant policy of treatment for many patients. The clinical course following initiation of treatment to date has been that of a remitting recurring disease, often with several biopsy-proven episodes of lymphadenopathy which are, albeit usually transiently, responsive to therapy. Transformation to diffuse large B-cell lymphoma occurs in up to 25% of patients over 15 years and usually heralds a grave prognosis, although this may be improving. Death occurs because of resistant disease, transformed or not, the complications of therapy, or unrelated causes. The median survival now exceeds 10 years. Prognostic factors are shown in Box 9.9.

Box 9.9 Prognostic factors in non-Hodgkin's lymphoma

Adverse factors:

- Age >60 years
- Stage III or IV, i.e. advanced disease
- High serum lactate dehydrogenase level
- Performance status (ECOG 2 or more)
- More than one extranodal site involved

ECOG, Eastern Cooperative Oncology Group.

Box 9.10 Indications for treatment of low-grade NHL at presentation or progression

- Stage I disease, possibly limited stage II disease
- Advanced disease, i.e. stage II–IV with 'B' symptoms
- Organ impairment (i.e. bone marrow failure)
- Bulky disease (i.e. lymph node mass >10 cm)
- Histological transformation
- Progression of lymphadenopathy after expectant management
- Philosophy of physician and patient

Management

General management

Lymph node biopsy accompanied by appropriate further investigation should precede any treatment decision. The 'well' patient variously defined, but certainly without symptoms, organ impairment, 'bulky disease' or evidence of rapid progression or transformation should, after a careful explanation of the rationale, be managed expectantly. This approach is followed by progression mandating therapy in about two and a half years for half the patients, with 20% having had some spontaneous regression and 15% having had no treatment, more than 10 years since diagnosis. A large trial comparing expectant management with immunotherapy with rituximab, however, shows a very considerable delay to having the first treatment in the rituximab group. The implications of this are unclear. Indications for treatment of low-grade non-Hodgkin's lymphoma are shown in Box 9.10.

Initial treatment: early disease

Stage I (possibly stage II): This is treated with involved field megavoltage irradiation, which almost always induces complete remission, with 50% being disease-free after 10–15 years. There are no randomized trials to show this is better in terms of overall survival than expectant management (i.e. observe and treat if progression occurs). Functional imaging, i.e. PET scanning, may identify patients who are in 'surgical CR' post-biopsy for whom no therapy is indicated.

Initial treatment: advanced disease (stages II–IV)

Chemoimmunotherapy incorporating rituximab is the treatment of choice having been shown in randomized trials to be superior to chemotherapy alone, in terms of disease-free, progression-free and overall survival. 'CHOP-R' (cyclophosphamide, doxorubicin, vincristine and prednisolone + rituximab) and the less intensive 'R-CVP' (rituximab + cyclophosphamide, vincristine and prednisolone) are both widely used and R-Bendamustine is gaining popularity. Over the next few years, it will become clear which chemotherapy is the best for which group of patients. It has been shown that continuing rituximab 'maintenance' for 2 years has a dramatic effect on progression-free survival, although as yet not on overall survival. If rituximab maintenance is not given, patients in complete or ('good') partial remission are managed

expectantly, until progression occurs. This is challenged by data showing that consolidation with radio-immunotherapy (^{90}Y trium anti-CD20) also prolongs disease-free survival. Trials are in progress to determine whether consolidation with myeloablative chemotherapy, with or without rituximab maintenance, improves outcome further.

Two studies have shown the efficacy of prolonged rituximab alone; the role of intensive therapy in standard practice is being questioned.

Second therapy and beyond

Patients are managed expectantly in the first instance, provided full re-evaluation, including repeat biopsy, reveals no evidence of transformation. A number of options are available, including re-induction of remission with combined chemoimmunotherapy, followed by rituximab maintenance in those not 'rituximab resistant'. Myeloablative consolidation chemotherapy is used in younger patients, particularly those in whom the first remission was short. Reduced-intensity conditioning allogeneic haematopoietic stem cell transplantation (HSCT) has yielded very impressive results in selected patients that may be curative despite the toxicity of the treatment.

The biggest challenges lie in patients with 'resistant disease' and in the treatment of 'transformation'. A number of experimental agents with new antibodies, immunomodulatory agents and drugs targeted to specific pathways are showing promise.

Summary

There has been a dramatic improvement in the overall survival pattern of follicular lymphoma as the result of introducing anti-CD20 (rituximab) in the treatment of advanced disease. The median survival has been extended, well beyond 10 years in several series, albeit possibly selected patients. Improvements in disease-free survival, both after initial and second-line therapy, are encouraging. It is reasonable to anticipate that further improvement will be seen with the selective use of allogeneic stem cell transplantation and the new targeted therapies under investigation.

Diffuse large B-cell lymphoma (DLBCL)

Introduction

This is the commonest lymphoma worldwide in the adult population (increasing in incidence with age) and the second commonest in childhood, accounting for approximately 30% of all cases. There is a slight male preponderance.

Clinical presentation

The majority of patients present with painless lymphadenopathy, clinically at one or several sites. Intra-abdominal disease presents with bowel symptoms due to compression or infiltration of the gastrointestinal tract. In a small proportion there is a primary mediastinal presentation, most often in men, with symptoms and signs akin to those of Hodgkin's lymphoma. There may be 'B symptoms', which should not be confused with symptoms related to the site of involvement. Investigation will lead to the demonstration of either locally or systematically advanced disease in the majority of cases. The illness is itself rapidly progressive, without intervention, death occurring within months rather than years. Approximately 30% present at an extranodal site as opposed to having nodal disease with extranodal spread.

Initial treatment

Treatment should be initiated immediately after the diagnosis is confirmed and in younger patients without co-morbidity

Figure 9.22 A predictive model for aggressive non-Hodgkin's lymphoma. Survival among the 1274 younger patients (≤ 60 years) according to risk group defined by the age-adjusted international index. L, low risk; LI, low-intermediate risk; HI, high-intermediate risk; H, high risk. (Reproduced with permission from: The International Non-Hodgkin's Lymphoma Prognostic Factors Project. A predictive model for aggressive non-Hodgkin's lymphoma. *New England Journal of Medicine* 1993; 329(14):987–994.)

Figure 9.23 Kaplan-Meier plot of overall survival of DLBCL patients grouped on the basis of gene expression profiling. (Reproduced with permission from Alizadeh AA. Distinct types of diffuse large B-cell lymphoma identified by gene expression profiling. *Nature* 2000; 403(6769):503–511.)

there is a high expectation of cure. Treatment is assigned on the basis of the International Prognostic Index (Box 9.9, Fig. 9.22).

Although this was constructed in the pre-rituximab era, it remains broadly applicable. Further refinement using gene expression profiling has identified at least two distinct subtypes of DLBCL (Fig. 9.23). Allopurinol is given routinely and also in some cases with different prognoses – germinal centre cell (GC) and activated B-cell (AB). A high proliferative index, aggressive prophylaxis against tumour lysis is indicated.

Low-risk (IPI score 0–1) with anatomically localized disease

At present, 'R-CHOP' followed by involved field irradiation, or 'more R-CHOP', are both used. Interim PET scanning may be used to inform individualization of therapy.

Two studies conducted in France suggest that the prognosis is better with chemotherapy alone provided 'enough' is given, with more than 80% of younger patients being alive 10 years after therapy. A trial comparing 'R-chemo' with 'chemo' in all patients with low-risk disease showed a marked advantage for those receiving chemoimmunotherapy. Further studies are awaited (Fig. 9.24).

Intermediate and poor-risk (IPI score 2+)

The age of the patient and co-morbidity are critical for both the selection of treatment and the prognosis. Recognition of this fact has led to the use of an age-adjusted prognostic index for patients over the age of 60. Chemoimmunotherapy

was established to be superior to chemotherapy alone for older patients in this category. 'R-CHOP', to a total of 6 or 8 cycles, has become standard care for the large majority of patients of all ages with DLBCL.

Many trials of increasing intensity of therapy for selected patients have yet to yield convincing results. However, there is an increasing consensus that the small group of patients having DLBCL with 'Burkitt-like features' should be treated as for Burkitt's lymphoma. The ability to distinguish between the molecularly distinct, 'germinal centre' and 'activated B cell', DLBCL with immunohistochemistry, has made it possible to explore different therapeutic approaches in the two groups, with appropriate targeted agents.

Involvement of the central nervous system, most often meningeal, is an uncommon but devastating complication, confirming a very poor prognosis overall. Patients with a high IPI score and particularly those with specific extranodal sites of involvement (testis, paranasal sinuses, bone marrow) and those who are HIV-positive should receive intrathecal methotrexate with each cycle of therapy. The management of overt leptomeningeal or parenchymal involvement, often in the context of generalized lymphoma, is difficult and usually unsuccessful in the long term. Most strategies involve high doses of systemic methotrexate and cytosine arabinoside, both of which cross the blood-brain barrier. Cranial or craniospinal irradiation is also used.

Second (and subsequent) therapy

Although there may be responsiveness initially to alternative chemotherapy, after failure of initial therapy or subsequent progression, the prognosis is very poor. Patients entering a partial remission do better than those who recur after entering an initial complete remission.

The major issues to be addressed are whether treatment is to be undertaken with palliative or curative intent and if the latter, the expectations of success. The *palliative approach* involves both chemotherapy and irradiation. The *curative approach* involves complete re-evaluation followed by

Figure 9.25 A child with Burkitt's lymphoma.

second-line chemotherapy, with a proven response rate of approximately 50%. If at least a further partial remission is achieved, in the younger, fitter patient, peripheral blood stem cell harvest is undertaken, followed, if successful, by an autograft. Overwhelmingly, the best results are achieved in those entering an unequivocal second complete remission. Even so, the proportion of patients in a prolonged second remission does not exceed 25%.

Prognosis

The outlook for patients with diffuse large B-cell lymphoma has improved by at least 15% in terms of cure, with the incorporation of rituximab into the initial therapy, the expectation of cure now being between 40% and 80% depending on the presenting features. The challenge of progressive disease following initial treatment is great, with overall less than 20% of patients alive long term.

Burkitt's lymphoma

Introduction

This is the most rapidly proliferating lymphoma with a doubling time approaching 100% and a very rapid evolution. The commonest childhood malignancy worldwide, it has a male:female preponderance of approximately 3:1 and occurs in all ages. There are three types:

- Endemic
 - always EBV-associated
 - occurring in equatorial Africa
 - corresponds to the distribution of malaria
- Sporadic
 - 30% EBV-related
- AIDS-related
- A similar picture to AIDS-related lymphoma may appear post-transplant.

The commonest presenting feature in the endemic type is a rapidly growing jaw tumour in a young child (Fig. 9.25). Otherwise, the next commonest is an abdominal mass often associated with bone marrow involvement. Other common sites are the central nervous system, the kidney and the testis. Investigation is along conventional lines for lymphoma, at least in the Western world, but must be conducted as a matter of urgency. A different staging classification is applied to children.

Management

Burkitt's lymphoma should be treated with curative intent whenever feasible, regardless of HIV status. Investigation having been completed, it is essential that the patient is

haemodynamically and metabolically stable prior to the initiation of specific therapy. Particular attention must be paid to the risk of the tumour lysis syndrome. Whenever possible, rasburicase prophylaxis should be given. If this is not available, other standard measures based on fluids and allopurinol to minimize the risk of tumour lysis syndrome should be pursued. Very frequent monitoring of electrolyte balance is essential for at least 72 hours after treatment is commenced, with particular attention to potassium and phosphate levels.

Standard treatment comprises if possible, intensive, cyclical combination chemotherapy, including cyclophosphamide, methotrexate and cytosine arabinoside in high doses. Rituximab is now included, although the evidence base for this is minimal. The details and number of cycles administered will be determined by the perceived level of 'risk'. Prophylactic central nervous system therapy is essential, intrathecal methotrexate or cytosine arabinoside often being given in addition to high-dose systemic administration. The chances of cure are very high for 'low-risk' patients and exceed 50% for 'poor-risk' patients as well, provided all treatment can be administered.

Failure to achieve complete remission is a very poor prognostic factor as is recurrence, which does so within the first year after completion of initial therapy if it is to happen. Although there may be further chemo-responsiveness, it is rare for second-line therapy to be more than transiently beneficial, regardless of whether it is followed by consolidation, with either myeloablative chemotherapy or allogeneic haematopoietic stem cell transplantation.

Summary

In the Western world, the prognosis of Burkitt's lymphoma has improved markedly over the past 10 years, with cure being the probability for the large majority at low risk and being substantial for those at high risk, including the HIV-positive cases.

Mantle cell lymphoma

This is one of the less common B-cell lymphomas, presenting usually in later life, with a male to female preponderance of 3:1. The commonest presentation is with painless lymphadenopathy, often generalized. There may be nonspecific symptoms of tiredness, or those related to the gastrointestinal tract. 'B' symptoms occur in <50%. Examination and standard investigation usually confirm generalized lymphadenopathy with or without hepatosplenomegaly (Fig. 9.26).

Figure 9.26 CT of the abdomen of a patient with mantle cell lymphoma showing significant splenomegaly.

Patients with bowel symptoms frequently have multiple lesions found on endoscopy. The bone marrow is usually involved and there may well be lymphoma cells in the peripheral blood.

Treatment

In the majority of patients, therapy is started after investigation has been completed. It is usual for there to be regression of disease with chemotherapy, although it is not often that complete remission is achieved. A prognostic index is used to help determine whether more or less 'aggressive' treatment is best employed. In reality, the major determining factors are the age of the patient and the presence or absence of co-morbidities. The outcome is likely to be best when 'more' treatment is given. Hence, younger, fitter patients are now treated with relatively intensive chemoimmunotherapy, incorporating rituximab, followed by, depending on its efficacy, myeloablative chemotherapy, with autologous stem cell rescue. Older, less fit patients are treated with less intensive therapy. In general, the strategy is to stop treatment after the planned initial course of treatment, provided the patient is well and at least a partial remission has been achieved. Almost inevitable progression for both older and younger patients occurs; palliation being the expectation for most. Experimental approaches include reduced intensity allogeneic haematopoietic stem cell transplantation and novel drugs targeting both the NFκB and mTOR pathways.

Summary

Mantle cell lymphoma is a lymphoma with a natural history untreated which lies between that of diffuse large B-cell lymphoma and follicular lymphoma. The prognosis has improved in recent years with the introduction of treatment strategies which have prolonged the period of remission without curing the patient and with the discovery of new 'effective' agents, making the overall median survival nearer 5 years.

Lymphoplasmacytic lymphoma

This is an uncommon, B-cell malignancy, which when associated with an IgM paraprotein and bone marrow infiltration is known as *Waldenström's macroglobulinaemia*. It usually occurs in later life, the incidence being approximately the same in men and women. It may be preceded by a pre-lymphomatous phase, in which a small, monoclonal IgM band is present, often an incidental finding, for many years. The presentation is with lymphadenopathy or alternatively with symptoms of anaemia or hyperviscosity due to the paraprotein (e.g. headaches, visual disturbance). Examination and investigation usually reveal little beyond minimal adenopathy and commonly splenomegaly.

Management

Following completion of investigation, the critical decision is whether to initiate specific therapy or not. A prognostic score is assigned, the critical decision being whether to initiate specific therapy or not. In an emergency, with severe symptoms of hyperviscosity, it is most appropriate to lower the paraprotein by plasmapheresis. In some circumstances, particularly in the otherwise less fit, it may be best to use maintenance pheresis and blood transfusion as the primary therapy. 'Responses' occur in about 50% of cases, with a fall in the paraprotein to 50% of the baseline level with single agent therapy and higher with combination chemotherapy and rituximab. The general strategy is to treat when it is clinically indicated and to stop after a conventional course of

FURTHER READING

Molyneux EM et al. Burkitt's lymphoma. *Lancet* 2012; 379:1234–1244.

treatment. Treatment, either repeating the initial therapy or changing, is re-instated only when progression is clearly documented, most often by fall in the haemoglobin or significant rise in the M-band and the illness is a threat to quality and quantity of life. In the very small proportion of younger patients for whom complete remission is achieved, consolidation with a bone marrow transplant is used. Similarly, in the same group of patients who have recurrent disease, which is again responsive, allogeneic haematopoietic stem cell transplantation is also used.

Prognosis

Lymphoplasmacytic lymphoma is a relatively rare chemotherapy- and immunotherapy-sensitive disease, which may have an indolent course for some years without therapy. Although the median survival is only 5 years, as it presents in later life, 10–20% of patients die of unrelated causes.

Primary extranodal lymphoma

Lymphoma may arise anywhere in the body where there is lymphoid tissue and therefore the clinical presentation is that of a lesion or mass at the relevant site. In practice the majority occur in the central nervous system, the stomach, or the skin.

Primary central nervous system lymphoma

This diffuse large B-cell lymphoma occurs in both the immunocompetent (predominantly the elderly) and the immunosuppressed, in the context of post-solid organ transplant or HIV infection. It presents with symptoms relating to single or multiple parenchymal mass lesions. The diagnosis needs to be made on the basis of a biopsy, particularly in the immunocompromised, in whom an infectious aetiology of the symptoms is possible, e.g. toxoplasmosis. *MRI scan* is the first choice investigation; cerebrospinal fluid is usually normal. Further investigation is necessary to exclude the cerebral lesion being a manifestation of generalized disease.

Treatment

In some patients in the post-transplant setting, reduction of immune suppression may be beneficial. Chemotherapy alone, with high-dose methotrexate and cytosine arabinoside, is used. Possibly, the best 'disease-free' results have been obtained by the use of chemotherapy and irradiation but toxicity is greater, with a risk of irreversible loss of cerebral function. The overall results are disappointing with only a small proportion of patients alive long-term without disability. The situation in the HIV-positive patient with cerebral lymphoma (fortunately a declining problem) is much worse and palliative irradiation is the best option.

Primary gastric lymphoma

This B-cell lymphoma, either extranodal marginal zone lymphoma of mucosa-associated tissue (MALT), or diffuse large B-cell lymphoma arising on a background of MALT lymphoma, is closely related to *Helicobacter* infection. It presents with symptoms of gastric ulceration or a mass, indigestion or bleeding and the diagnosis is made by endoscopic biopsy to include both the confirmation of lymphoma and *H. pylori* status. This is followed by investigation as for nodal lymphoma, which reveals local nodal involvement in a proportion of patients and distant spread in only a small number. Treatment is entirely dependent on whether or not there is any evidence of diffuse large B-cell lymphoma. If only 'low-grade' gastric 'MALT' lymphoma is present, *Helicobacter* eradication therapy is the treatment of choice (p. 249). This almost invariably alleviates the symptoms. Re-evaluation after 3 months with endoscopy, repeat biopsy and in some circumstances, endoscopic ultrasound is carried out. In general, a

conservative approach is followed, as responses may take many months to achieve and rapid progression is very unlikely. Regular endoscopy 6-monthly should be continued for at least 2 years. Failure is not common and if it occurs, it is rarely rapid. If it occurs, the biopsy should be repeated. If the histology is unchanged after further *Helicobacter* eradication therapy (if necessary) either irradiation to the gastric bed or chemoimmunotherapy is likely to be effective or possibly curative. Overall, the prognosis is very good, the very large proportion of patients being alive 10 years after diagnosis.

Any evidence of diffuse large B-cell lymphoma is an indication for chemoimmunotherapy. *Helicobacter* eradication therapy should also be given, but should not be considered definitive treatment. The potential risk of gastric perforation or haemorrhage because of therapy is not a contraindication to treatment. Surgery is rarely needed, but irradiation is used for persistent disease. The prognosis is approximately the same as for nodal DLBCL of equivalent extent.

Primary cutaneous lymphoma (T or B cell)

Lymphomas of both B- or T-cell type may arise singly and multiply in the skin and pursue a very long natural history even though they may give rise to considerable discomfort.

Mycosis fungoides, Sézary syndrome

This is the commonest cutaneous lymphoma, predominantly arising in and confined to the skin, although later in the disease spreading to other organs. It has a long natural history, being sometimes preceded by a scaly 'pre-mycotic phase'. This T-cell lymphoma presents with multiple erythematous lesions, plaques and tumours, which when associated with spread to the blood, become the Sézary syndrome. Generalized erythema may occur (erythroderma). The likelihood over time of disease extending beyond the skin is highest in patients with tumours.

Treatment is palliative and there is little indication that the disease is ever eradicated. Many treatments result in regression of disease. Antibiotics are used for infection. Phototherapy (PUVA), topical steroids and topical chemotherapy all lead to response. Radiation is effective and total skin electron beam therapy particularly so, although attention must be given to potential side-effects including erythroderma. Systemic chemotherapy, either at conventional or high doses, has been disappointing. Newer approaches include anti-T-cell antibodies and histone deacetylase inhibitors. The median survival is approximately 10 years, there being close correlation with the extent of disease at presentation. Interaction between oncologist and dermatologist is essential.

Cutaneous B-cell lymphoma

The two major subtypes are extranodal marginal zone and follicle centre in origin. Both usually present with either single or clustered cutaneous lesions, biopsy of which confirms the diagnosis. All conventional staging investigations are negative. Treatment is either expectant, surgical excision or irradiation, which may be used repeatedly over time. Antibiotics are used for marginal zone lymphoma if there is evidence of *Borrelia burgdorferi* infection. Only if there are lesions at multiple sites should systemic chemotherapy be used. The long-term prognosis is excellent.

T and natural killer (NK) cell lymphomas

(Fig. 9.27)

Introduction

These are much less common than their B-cell counterparts, although they are relatively more frequent in the East than

Figure 9.27 Relative frequencies of T-cell lymphoma subtypes in adults. NOS, not otherwise specified. (Reproduced with permission from WHO. Swerdlow SH, Campo E, Harris NL et al. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, 4th edn. Geneva: WHO; 2008; Fig 8.07.)

the West. The commonest presentations are nodal or cutaneous (p. 1226) and specific subtypes involve the liver and subcutaneous tissue. Peripheral T-cell lymphomas with nodal presentation have a poor prognosis. They are treated as DLBCL without rituximab.

The two 'commonest subtypes' of 'nodal' T-cell lymphoma are peripheral T-cell lymphoma, 'not otherwise specified' (NOS) and angioimmunoblastic T-cell lymphoma, which together account for about 50% of T-cell lymphomas. Both occur in the middle-aged to elderly population, the primary presentation being lymphadenopathy. In contrast to the B-cell lymphomas, 'B symptoms' are common. Patients with angioimmunoblastic T-cell lymphoma also present with features akin to inflammatory disease, with fevers, rashes and electrolyte abnormalities, which in the first instance may be rapidly responsive to corticosteroids or low doses of alkylating agents.

Management

Following standard investigation, which usually reveals widespread disease, patients are treated with cyclical combination chemotherapy as used for diffuse large B-cell lymphoma. CD20 is not expressed on T cells so rituximab is not used and, as yet, there is no equivalent drug for T-cell lymphoma. Resolution of symptoms almost invariably occurs, although they may recur between cycles. Overall, the outcome of treatment is worse than for DLBCL, in terms of quality of response, duration of response and overall survival. Second-line therapy is rarely satisfactory, although a small proportion of patients may benefit from myeloablative therapy to consolidate a second response.

MYELOMA

Myeloma is a malignant disease of bone marrow plasma cells, accounting for 1% of all malignant disease. There is a clonal expansion of abnormal, proliferating plasma cells producing a monoclonal paraprotein, mainly IgG (55%) or IgA (20%) and rarely IgM and IgD. The paraproteinaemia may be associated with excretion of light chains in the urine (Bence Jones protein), which are either kappa or lambda. In approximately 20%, there is no paraproteinaemia, only light chains in the urine. Rarely, patients produce no paraprotein or light chains – 'non-secretory myeloma' (<5%).

Clinicopathological features

Myeloma is a disease of the elderly, the median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100 000 and it is commoner in males and in black Africans but less common in Asians. The clinical features include:

- Bone destruction, often causing fractures of long bones or vertebral collapse (which can cause spinal cord

Mu (μ) heavy chain disease
Alpha (α) heavy chain disease

compression) and hypercalcaemia. Soft tissue plasmacytomas also occur and they are the usual cause of spinal cord compression in myeloma

- Bone marrow infiltration with plasma cells, resulting in anaemia, neutropenia, thrombocytopenia, together with production of the paraprotein which may (rarely) result in symptoms of hyperviscosity
- Kidney injury (see p. 1043) owing to a combination of factors – deposition of light chains in the renal tubules, hypercalcaemia, hyperuricaemia, use of NSAIDs and rarely the deposition of AL amyloid.

In addition, there is a reduction in the normal immunoglobulin levels (immune paresis), contributing to the tendency for patients with myeloma to have recurrent infections, particularly of the respiratory tract. The WHO classification (2008) of plasma cell neoplasms is shown in Table 9.29.

Cytogenetics

With fluorescence *in situ* hybridization and microarray techniques abnormalities are found in most cases of myeloma. Abnormalities of chromosome 13 and hypodiploidy (<45 chromosomes) have been shown to be associated with poor survival, as have t(4; 14), t(14; 16) and p53 (17p) deletions; t(11; 14) and hyperdiploidy (>50 chromosomes) are associated with a better prognosis.

Bone disease

There is dysregulation of bone remodelling, which leads to the typical lytic lesions, usually seen in the spine, skull, long bones and ribs. In myeloma there is increased osteoclastic activity with no increased osteoblast formation of bone. Bisphosphonates that inhibit osteoclast activity are useful in myeloma but surprisingly there is no increase in bone deposition (see below).

Adhesion of stromal cells to myeloma cells stimulates the production of RANKL, IL-6 and also VEGF, which plays a role in angiogenesis. RANKL also stimulates osteoclast formation and the lytic lesions. Myeloma cells also produce dickkopf-1 (DKK1), which inhibits osteoblast activity and therefore production of new bone. This occurs because DKK1 binds to the Wnt co-receptor, lipoprotein receptor-related protein 5

Box 9.11 Life-threatening complications of myeloma

- Renal impairment – often a consequence of hypercalcaemia – requires urgent attention and patients may need to be referred for long-term peritoneal or haemodialysis
- Hypercalcaemia should be treated by rehydration and use of bisphosphonates such as pamidronate
- Spinal cord compression due to myeloma is treated with dexamethasone, followed by radiotherapy to the lesion delineated by a magnetic resonance imaging (MRI) scan
- Hyperviscosity due to high circulating levels of paraprotein may be corrected by plasmapheresis.

(LRP5), inhibiting Wnt signalling (see p. 26) and osteoblast differentiation.

Symptoms

- Bone pain – most commonly backache owing to vertebral involvement (60%)
- Symptoms of anaemia
- Recurrent infections
- Symptoms of renal failure (20–30%)
- Symptoms of hypercalcaemia
- Rarely symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by 'routine' abnormal blood tests. Life-threatening complications are shown in Box 9.11.

Investigations

General

- **Full blood count.** Hb, WCC and platelet count are normal or low.
- **ESR.** This is often high.
- **Blood film.** There may be rouleaux formation as a consequence of the paraprotein and circulating plasma cells in the aggressive plasma cell leukaemia variant of myeloma.
- **Urea and electrolytes.** There may be evidence of kidney injury (see above).
- **Serum calcium** is normal or raised. Serum alkaline phosphatase is usually normal.

Immunological

- Total protein is normal or raised.
- Serum protein electrophoresis and immunofixation characteristically shows a monoclonal band and immune paresis (Fig. 9.28). The serum free light chain assay, more sensitive than urine electrophoresis, may show an abnormal ratio and an increased total amount of free kappa or lambda chains and is often abnormal earlier than routine electrophoresis.
- 24-hour urine electrophoresis and immunofixation is used for assessment of light-chain excretion.

Radiological

- **Skeletal survey.** This may show characteristic lytic lesions, most easily seen in the skull (Fig. 9.29). CT, MRI and PET are used in plasmacytomas (bone or soft tissue deposits). MRI spine is useful if there is back pain – may show imminent compression/collapse.

Other

Bone marrow aspirate or trephine shows characteristic infiltration by plasma cells (Fig. 9.30). Amyloid may be found (see p. 1043).

Figure 9.28 Immunofixation and electrophoresis.

(a) Immunofixation IgG kappa monoclonal paraprotein. (b) Quantitation and serum electrophoresis IgG paraprotein. Serum electrophoresis and immunofixation of a patient with an IgG K paraprotein (left). The column on the far left is the total serum electrophoresis stained with anti-protein reagents. Albumin is at the top with the increased immunoglobulins at the bottom. These are shown to stain with anti-IgG and anti-kappa light chain reagents. The paraprotein is quantified (right) by calculating the area under the paraprotein spike and comparing it with the albumin concentration.

Box 9.12 International prognostic index based on serum albumin + $\beta 2$ microglobulin ($\beta 2M$)

Stage	Median survival (months)
Stage 1 – $\beta 2M < 3.5$ mg/L and serum albumin ≥ 35 g/L	62
Stage 2 – not stage 1 or 3	44
Stage 3 – $\beta 2M > 5.5$ mg/L	29

Prognostic factors

Reduced serum albumin, increased serum $\beta 2$ -microglobulin and increased serum lactate dehydrogenase (LDH).

Diagnosis

Symptomatic myeloma (SMM) can be diagnosed if either of the following are present:

- Significant paraproteinaemia
- Increased bone marrow plasma cells ($>10\%$);

with evidence of end organ failure, i.e. hypercalcaemia, renal impairment, anaemia, lytic bone lesions (CRAB).

An international prognostic index based on serum albumin + $\beta 2$ microglobulin ($\beta 2M$) at diagnosis is used for prognostic information (Box 9.12).

Asymptomatic myeloma (AMM) (10% cases) has a significant paraprotein (IgG or IgA >30 g/dL or urinary light chain excretion >1 g/day) and/or a marrow plasmacytosis $>10\%$ but no end organ damage. The median time to progression for these patients is 2–3 years. The risk is highest for those with IgA isotype and light chains in the urine

Monoclonal gammopathy of unknown significance (MGUS). MGUS describes an isolated finding of a monoclonal paraprotein in the serum, usually in the elderly, that does not fulfil the diagnostic criteria for SMM or AMM. 20–30% go on to develop multiple myeloma over a 25-year period. Low-risk MGUS is characterized by those with an IgG subtype, a paraprotein <15 g/dL and a normal serum free light chain ratio.

Plasmacytoma. Patients may present with an isolated tumour of neoplastic plasma cells called a plasmacytoma and no evidence of multiple myeloma. This may be a 'solitary plasmacytoma of bone' within the skeleton or an 'extramedullary plasmacytoma' outside the marrow cavity typically in the upper aerodigestive tract.

For paraprotein associated neuropathy and POEMS, see page 1079.

Treatment

With good supportive care and chemotherapy, median survival is now 5 years with some patients surviving to 10 years. Young patients receiving more intensive therapy may live longer.

Supportive therapy

- Anaemia should be corrected; blood transfusion may be required. Erythropoietin often helps. Transfusion should be undertaken slowly in patients with hyperviscosity.
- Hypercalcaemia, kidney injury and hyperviscosity should be treated as indicated (see *Acute oncology* p. 448 and *Acute kidney injury* p. 609).
- Infection should be treated promptly with antibiotics. Give yearly flu vaccinations.
- Bone pain can be helped most quickly by radiotherapy and systemic chemotherapy or high-dose

dexamethasone. NSAIDs are usually avoided because of the risk of acute kidney injury. Bisphosphonates, e.g. zoledronate, which inhibit osteoclast activity, help ensure rapid normocalcaemia and, given long term, reduce skeletal events such as pathological fracture, cord compression and bone pain.

- Pathological fractures may also be prevented by prompt orthopaedic surgery with pinning of lytic bone lesions at critical sites seen on the skeletal survey, e.g. femoral shaft. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures (p. 505).

Specific therapy

Myeloma remains incurable. Therapy is aimed at treatment of specific complications, prevention of these and prolongation of overall survival. Thalidomide has activity as a single agent and is widely used in first-line and relapsed settings. It is teratogenic and associated with neuropathy, somnolence, constipation and an increased risk of venous thrombosis.

In younger patients (<65 – 70 years), an orally active cyclophosphamide, thalidomide and dexamethasone-based induction (CTD), followed by a high-dose melphalan autograft, has a significantly higher response rate with 40% of patients achieving a CR with median survival increasing to 6 years. The role of allogeneic transplant is currently unclear. In older or less fit patients, melphalan and prednisolone was used, with a median survival of 29–37 months; complete remissions are rare. Recent phase III studies have suggested that this, combined with thalidomide, results in improved response rates and overall survival, albeit with increased toxicity.

For relapsed patients, a second autograft may be considered if there was a favourable response duration to the first (>12 – 18 months). Bortezomib is a proteasome inhibitor, which is licensed for relapsed myeloma. Thalidomide, lenalidomide and bortezomib all show synergy with dexamethasone and chemotherapy and several phase II studies have shown very promising activity in newly diagnosed patients. One phase III study has shown that bortezomib plus melphalan and prednisolone (VMP) is superior to the latter two alone. Lenalidomide is a thalidomide analogue, which is also used for relapsed myeloma. It has greater potency than thalidomide with less toxicity.

COMMON SOLID TUMOUR TREATMENT

Common solid cancer mortality is listed in Table 9.1; the improvements in survival over the past 10 years have come from advances in both prevention, diagnosis and treatment (Fig. 9.31). The presentation, diagnosis, natural history and systemic treatment of the common cancers are described in the relevant chapters. The decision to treat and the aim of that treatment, whether for palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient's performance status and the potential efficacy of treatment. Management should be carried out by multidisciplinary teams, usually led by an oncologist.

Lung cancer

The presentation and diagnosis of lung cancer (Fig. 9.32) are more fully covered in the chapter on respiratory disease (see p. 856). The current treatment reflects the fact that the

majority of patients are diagnosed at an advanced stage with a poor prognosis and therefore there are many trials assessing different screening strategies to try and achieve earlier diagnosis and more curative treatment.

Prognostic factors

Lung cancer histology is divided into two main types: small-cell (neuroendocrine) lung cancers (SCLC), which tend to disseminate early in their development, and non-small-cell lung cancers (NSCLC), which are more likely to be diagnosed in a localized form. Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 15%, treatment is beginning to have

an impact in selected groups and the multidisciplinary team can greatly aid in the appropriate application of treatment and the avoidance of nihilism.

Non-small-cell lung cancer

The staging has been improved by CT and PET scanning and is classified according to the TNM system (see Table 15.29; Fig. 15.44), by which the disease can be divided into local, locally advanced and advanced stages with 5-year survival varying from 55–67%, to 23–40%, to 1–3%, respectively.

Treatment

Surgery can be curative in non-small-cell lung cancer (T1, N0, M0) but only 5–10% of all cases are suitable for resection; about 70% of these survive for 5 years. Surgery is rarely appropriate in patients over 65 years, as the operative mortality rate exceeds the 5-year survival rate. Trial data suggest that neoadjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation.

Preoperative assessment: lung function tests, including walking oximetry, are used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

In operable disease stages T1N0 to T3N2 (stage I to IIIa), adjuvant radiotherapy and chemotherapy following surgery can improve prognosis in patients of good performance status as shown by the international adjuvant lung cancer trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival for stage II and IIIa disease of 4% from 40.4% to 44.5%.

A practical molecular assay to predict survival in resected non-squamous lung cancer is becoming available.

Radiation therapy for cure

In patients who are fit and who have a stage 1 NSCLC, high-dose radiotherapy (65 Gy or 6500 rads) can result in a 27-month median survival and a 22% 5-year survival. It is the treatment of choice if surgery is not appropriate; however, poor lung function can also be a relative contraindication to radiotherapy. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases but is usually asymptomatic.

For unresectable disease, the combination of concurrent cisplatin with radiotherapy (chemoradiation) when compared with radiotherapy alone has increased the resection rate and 3-year survival from 11% to 23%, at the expense of greater oesophageal toxicity.

In advanced disease, cisplatin or carboplatin in combination with one other drug such as paclitaxel or gemcitabine for 12 weeks, produces a symptomatic improvement in 40% and increases median survival from 6 to 10 months, compared with best supportive care, with 10–20% alive at 1 year.

In the future, molecularly targeted treatment for lung cancer is becoming a possibility. Activating mutations (del exon 19 and L858R point mutation) in EGFR in 10% of adenocarcinomas confer sensitivity to erlotinib and gefitinib and 5% of NSCLC (mostly non-smoking associated adenocarcinoma) carry mutated anaplastic lymphoma kinase (ALK) genes conferring sensitivity to the receptor tyrosine kinase inhibitor crizotinib.

Small-cell lung cancer

Prognostic factors

The staging of small-cell lung cancer is divided into limited and extensive disease according to whether or not it is confined to a single anatomical area or radiation field. Systemic therapy is the primary therapeutic modality because of the usually disseminated nature of the disease.

Treatment

Limited disease is present in approximately 30% of patients and is best treated with concurrent chemo- and radiotherapy using a combination of cisplatin and etoposide or irinotecan, which increases the survival at 5 years from 15% to 25%, compared with radiotherapy alone. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic CNS disease and improve overall survival by 5%.

Extensive disease can be palliated with the combination of carboplatin and etoposide or irinotecan, which when compared with best supportive care, can increase median survival from 6 months to 9–13 months and the 2-year survival to 20%.

Symptomatic care for lung cancer patients

The prognosis for the majority of patients remains poor because the disease is diagnosed in an advanced stage and the co-morbidity from other smoking-related disease compromises treatment. Therefore, much of the treatment whether symptomatic or anticancer is delivered with palliative intent. (General palliative care is discussed in [Chapter 10](#).) Specific issues for lung cancer are the relief of bronchial obstruction and breathlessness and the relief of local pain for which radiotherapy is often employed alongside appropriate opiate analgesia. Laser therapy, endobronchial irradiation and tracheobronchial stents are used (see [p. 862](#)).

Metastases in the lung

Metastases are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but may be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases develop in the parenchyma or pleura usually and are often relatively asymptomatic even when the chest X-ray shows extensive disease. Rarely, metastases may develop within the bronchi and present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. Chest X-ray signs of hilar lymphadenopathy and basal shadowing are unreliable compared with the characteristic signs on CT scan of irregular thickening of the interlobular septa in a polygonal pattern around a thick-walled central vessel.

Occasionally, a pulmonary metastasis may be detected as a solitary round shadow on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- Primary bronchial carcinoma
- Tuberculoma
- Benign tumour of the lung
- Hydatid cyst.

Table 9.30 Breast cancer histology

Non-invasive

Ductal cancer *in situ*

Other

Adenoid cystic, secretory, apocrine cancers
Paget's disease of the nipple
Phyllodes tumour

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging including PET scanning and assessment is essential before undertaking surgery.

Breast cancer

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK, with biplanar digital mammography every 3 years in women aged 50–70, and improvements in multimodality treatment have improved overall survival and rates of cure, while breast-conserving surgery has greatly ameliorated the psychosexual impact of the disease.

Aetiology and pathology

The majority of breast cancers arise from the epithelial cells of the milk ducts and reproduce their histological features in a variety of patterns ([Table 9.30](#)), of which the most common is an infiltrating ductal carcinoma. The molecular biology of breast cancer has revealed that further subdivision based on resemblance to basal, luminal A, or luminal B type ductal cells is associated with differing behaviour. For example the oestrogen receptor (ER), negative, progesterone receptor (PR) negative, mutated EGFR (Her2) negative, triple negative phenotype corresponds to a portion of the basal cell population and is associated with a worse prognosis than the luminal types. Some triple negative cancers also resemble the BRCA1 mutated cancers with an associated DNA repair deficiency which has been targeted with new drugs such as PARP inhibitors. For many cancers it is thought that there is an identifiable precursor *in situ* stage which is confined within the basement membrane and is still truly localized and detectable by its trademark microcalcification on a screening mammogram. For others, this stage may be so brief or non-existent as to not be detectable and invasive disease is present from very early in development with a consequently worse prognosis. Approximately 10% of women have familial breast cancer ([Table 9.31](#)) and 3% have detectable mutations in the BRCA1 and 2 genes and TP53. The hormonal environment exerts a major effect on the expression of the breast cancer potential and is related to reproductive behaviour, diet, exercise, weight and exogenous hormones from oral contraception and postmenopausal hormone replacement therapy.

Symptoms and signs

Most women with symptomatic rather than screen-detected breast cancer present with a painless increasing mass which may also be associated with nipple discharge, skin tethering,

One close relative with ovarian cancer and one with breast cancer, diagnosed at any age – at least one must be a mother, sister or daughter
Close relative of Ashkenazi Jewish origin with breast or ovarian cancer

ulceration and, in inflammatory cancers, oedema and erythema. In developing countries, 80% are likely to present with advanced disease and metastases.

Investigations

The triple assessment of any symptomatic breast mass by palpation, radiology (mammography, ultrasound and MRI scan) and fine-needle aspiration cytology is the most reliable way to differentiate breast cancer from the 15 times more common benign breast masses. Large bore core needle biopsy should follow to provide histological confirmation and predictive factors such as grade, Ki-67 proliferation index and oestrogen, progesterone and Her2 receptor status to inform the subsequent decision-making process. Assessment should be carried out in a dedicated one-stop clinic able to provide the appropriate support and referral. Staging is both surgical with respect to tumour size and axillary lymph node status and, in advanced disease, by investigation of common sites of metastasis by chest X-ray and CT scan of lungs and liver and bone scan. At present, only 20% of patients are diagnosed with no evidence of microscopic nodal metastases.

Prognostic factors

The following are all significant independent predictors of risk of recurrence: size of the primary tumour; the histological subtype (most are infiltrating ductal carcinoma); histological grade/differentiation; oestrogen and progesterone receptor (ER, PR) status; patient age and menopausal status. Expression of Her2 is an adverse factor for small otherwise good prognosis tumours and like ER and PR is a predictor of treatment response.

Gene expression profiles have identified sets of between 20 and 70 genes, the expression pattern of which can identify low- and high-risk subsets independent of the clinical risk factors. Clinical trials are in progress to test whether this leads to better decision-making and outcome than the traditional clinical factors.

Early breast cancer

Survival probability and benefit from adjuvant treatment can be calculated using the website: www.adjuvantonline.com, which is based on the American Surveillance Epidemiology and End Results (SEER) database and has been validated on independent datasets from British Columbia and Finland. The estimated 10-year survival probability following surgery alone will vary from 93–99% for small (<1 cm) low-grade

node-negative tumours to only 10% for large high-grade tumours with more than nine axillary nodes involved.

Local treatment

Surgery may vary from wide local excision or segmental mastectomy and breast conservation for masses <3 cm in diameter, to simple mastectomy with or without reconstruction. The choice is dictated by the location and extent of the breast mass in relation to the breast size and patient preferences. In the absence of clinical or radiological (usually ultrasound) evidence of lymphadenopathy, surgery of the axilla can be minimized by sentinel lymph node guided sampling (after dye or radioactive tracer injection); otherwise dissection to level 3 is required if there are clinically involved nodes in order to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery, the greater the risk of postoperative lymphoedema.

Radiotherapy is given to the conserved breast after wide local excision to reduce local recurrence and to the chest wall after mastectomy if there are risk factors for local recurrence to complete the local control measures. The indications for breast cancer adjuvant radiotherapy are:

- Breast conserving surgery
- Large high-grade primary tumour
- Proximity to surgical margins
- >2 Lymph node metastases.

Radiotherapy to the axilla can be added after sampling but not after full dissection of the axilla because the combination raises the risk of severe lymphoedema to 30%. Adjuvant radiotherapy reduces the risk of local recurrence by 25% and improves 10-year survival by 3%.

Recent data suggest that women over 70 years with oestrogen receptor positive cancers up to 2 cm diameter may be offered surgery and tamoxifen alone without radiotherapy, without compromising outcome.

Endocrine treatment

Premenopausal women

In *premenopausal women*, a reduction in oestrogens can be achieved by oophorectomy or via pituitary downregulation using a gonadotrophin-releasing hormone (GnRH) analogue such as goserelin or leuprorelin.

Tamoxifen is a mixed agonist and antagonist of oestrogen action on the ER while the more recent drug fulvestrant is a more selective oestrogen receptor modulator (SERM).

Synthetic progestogens, e.g. medroxyprogesterone acetate and megestrol acetate, have a direct effect on breast tumour cells through progesterone receptors, as well as effects on the pituitary/ovarian (premenopausal) and adrenal/pituitary axis (postmenopausal). They can be as effective as tamoxifen in metastatic breast cancer

Postmenopausal women

In *postmenopausal women*, androgens are synthesized by the adrenal glands and converted in subcutaneous fat to estrone by the enzyme aromatase. The aromatase inhibitors, anastrozole, letrozole and exemestane, reduce circulating oestrogen levels and oestrogen synthesis in tumour cells and have shown greater efficacy than tamoxifen in the treatment of metastatic breast cancer and equivalence in the adjuvant setting.

Side-effects (Table 9.32) are those of oestrogen deprivation and women need support in managing them if they are to be able to complete the standard 5-year course.

- Positive nodes

Adjuvant systemic treatment**Endocrine**

In about one-third of patients, the breast cancer will express receptors for oestrogen and progesterone. For premenopausal women tamoxifen adjuvant therapy immediately following surgery for receptor-positive disease reduces the 10-year relative risk of women dying from breast cancer by about 25% and the absolute 10-year death rate by an average of 12% for all stages.

For postmenopausal women with oestrogen and/or progesterone receptor-positive disease, adjuvant tamoxifen or aromatase inhibitors (AIs) such as anastrozole, letrozole, or exemestane all given for 5 years, reduce the risk of death from breast cancer by a similar 25%.

Aromatase inhibitors, however, are the treatment of choice for postmenopausal women because they avoid the adverse effects of tamoxifen on the uterus and venous thromboembolism and achieve a greater reduction in contralateral breast cancers and in distant metastases contributing to an overall improvement in relapse-free survival though not an overall survival advantage. Both tamoxifen and aromatase inhibitors cause symptoms of oestrogen deprivation (see above), but whereas tamoxifen has a beneficial effect upon serum lipid profiles the reverse is true of AIs leading to concerns over their long-term effects on women's cardiovascular health. It is recommended that the choice should be discussed for each patient taking the individual co-morbidities into account. The effects of endocrine therapy are additive to those of chemotherapy and most effective given following, not concurrently with, the chemotherapy.

Chemotherapy and targeted therapy

A meta-analysis of all randomized trials of adjuvant therapy in breast cancer has shown that for women with high-risk features (Box 9.13), adjuvant chemotherapy with first generation regimens such as CMF (cyclophosphamide, 5-fluorouracil plus methotrexate) for 6 months, reduces the absolute 10-year death rate by about 10% and the relative risk of death by 20%. Ovarian ablation by a GnRH analogue for 2 years is equally as effective as CMF chemotherapy in premenopausal women. More effective second generation regimens with an anthracycline such as epirubicin (Epi-CMF) or FEC100 (5-fluorouracil, epirubicin 100 mg/m², cyclophosphamide) increase this to 25%. A third generation regimen

with a taxane, e.g. FEC-D (fluorouracil, epirubicin, cyclophosphamide followed by docetaxel) (Table 9.11), gives a 33% relative risk reduction but has increased toxicity.

Chemotherapy is less effective in hormone receptor positive disease and although menopausal status does not affect the relative efficacy of chemotherapy the risk of recurrence is lower after the menopause and thus the absolute improvement in survival is less. Toxicity may also be higher in this age group, especially over the age of 70, so that treatment decisions may need to be more individualized in discussion between the patient and her doctors. The combined effect of radiotherapy, chemotherapy and tamoxifen or aromatase inhibitor approximately halves the risk of dying of breast cancer for appropriately selected patients.

Her2/c-erbB2 targeted therapy

The addition of adjuvant i.v. trastuzumab for a further year to chemotherapy for the treatment of the 15–20% of patients in whom the breast cancer overexpresses Her2 further reduces the risk of mortality by 25% for trastuzumab alone and by 33% when administered concurrently with a taxane. Trastuzumab is the standard of care for these patients but has a direct toxic effect upon the myocardium that is additive to pre-existing myocardial damage, especially that caused by anthracyclines, and should not be given concurrently. An alternative regimen with docetaxel, carboplatin and trastuzumab is equally as effective and can avoid much of the myocardial toxicity. Left ventricular ejection fraction must be monitored before and during treatment to avoid potentially severe congestive heart failure.

Alternative approaches which block the Her2 signalling with a different monoclonal antibody pertuzumab or the receptor tyrosine kinase inhibitor lapatinib are also proving successful and dual combination with trastuzumab holds promise for preventing the development of resistance to these targeted therapies.

Neoadjuvant and primary systemic treatment

There is no survival advantage for preoperative endocrine or chemotherapy treatment when compared with postoperative treatment, i.e. the advantage over surgery alone is the same; however, there is a significant benefit from either rendering inoperable tumours operable (called primary systemic therapy) or large tumours smaller and suitable for breast conserving surgery in about one-third of such patients (called neoadjuvant therapy), in addition to the reduction in risk of death from distant metastases.

Advanced breast cancer

Patients with established metastatic disease may require endocrine therapy, chemotherapy and radiotherapy. The treatment is not curative but is of great palliative benefit and consistent often with many years of good-quality life. Little additional benefit has been gained by adding endocrine and chemotherapy together, although the addition of anti-HER2 (antibodies) to chemotherapy has produced a survival advantage. Prolonging treatment can delay relapse but at the expense of treatment toxicity and, therefore, the serial use of intermittent courses of the different endocrine and chemotherapies starting with the least toxic, most effective treatment seems most consistent with maintaining a good quality of life for as long as possible.

Endocrine therapy

Women who have high levels of oestrogen receptors (ER) and progesterone receptors (PR) in their tumour have a greater chance of responding to endocrine treatments (i.e. 60%

versus 10% for ER negative disease). Endocrine responsive disease characteristics are:

- Expression of ER and/or PR
- Disease-free interval >1 year
- Skin, lymph node or bone disease
- Absence of life-threatening visceral disease.

Endocrine therapy is usually tried first in those patients who have characteristics suggesting they are likely to respond and who do not have immediately life-threatening organ failure. Remission lasts on average 2 years and is consistent with an excellent quality of life. When relapse occurs, further treatment with different agents may produce another remission.

Chemotherapy

Chemotherapy is used for patients who lack the above features of hormone responsive disease or who fail to respond to endocrine therapy or who require a rapid response if at risk of, e.g. liver or respiratory failure. Chemotherapy can provide good-quality palliation and prolongation of life. The drugs listed below are all able to induce objective responses in metastatic disease and patients in whom the disease responds are likely to experience further serial responses to subsequent treatment at relapse. There is no advantage in combining more than two drugs at a time and considerable uncertainty over the advantages of combinations with higher response rates but only rarely better survival compared with single agent regimens which have the advantage of preserving more options for future use. There is very little difference in efficacy between the different regimens for metastatic disease, with response rates varying from 40% to 60% for median duration of 8–10 months. The most common regimens with either single agents or doublet combinations include:

- MM: mitoxantrone and methotrexate
- AC/EC: doxorubicin or epirubicin and cyclophosphamide
- DC: docetaxel and capecitabine
- PG: paclitaxel and gemcitabine
- Vinorelbine, carboplatin, mitomycin and eribulin.

The multiple regimens provide the possibility of avoiding drug resistance over several episodes of treatment interspersed with treatment-free periods so that the disease can be palliated, often for several years.

The addition of trastuzumab and more recently lapatinib to the cytotoxic drugs (except the anthracyclines, see above) has significantly improved survival for those women whose tumour overexpresses the c-erbB2/Her2 oncogene. Inhibition of VEGFR by bevacizumab may be effective in a small proportion of patients but it is without as yet a predictive biomarker. Markers of DNA repair deficiency such as BRCA1 mutations render the breast cancer especially sensitive to the PARP inhibitor olaparib.

Bisphosphonate therapy

Bone metastases are a common problem in the management of breast cancer and the bisphosphonates have a major role in reducing the incidence of osteolytic deposits, bone pain and fracture when used preventatively and in treating pain and hypercalcaemia from established metastases. Second generation bisphosphonates pamidronate and oral clodronate are often sufficient. The more potent third generation drugs such as zoledronate and oral ibandronate may require less frequent administration but can be associated with impaired bone healing and osteonecrosis of the jaw (see [Chapter 11](#)).

Denosumab is a MAb to the RANK ligand that inhibits osteolysis and is equally effective as bisphosphonates.

Gastrointestinal cancer

Presentation and diagnosis are described in Gastrointestinal disease, see [Chapter 6](#).

Upper gastrointestinal**Oesophageal cancer**

Early diagnosis as pioneered in Japan, where there is a particularly high incidence, has shown that it is possible to improve the prognosis of a disease otherwise typically only diagnosed when local metastases have already occurred.

Treatment and prognostic factors

Histology, stage, age and performance status are critical prognostic factors for treatment decisions, which should be made by a multidisciplinary team in designated units with the surgical expertise to avoid treatment mortality. The prognosis for the majority of symptomatic patients is poor, 50% have distant metastases at the time of diagnosis and the majority of the remainder will have loco-regional spread into adjacent mediastinal structures. Staging with endoscopic ultrasound and CT-PET scans has improved the selection of patients of good performance status with truly localized disease for whom curative treatment may be attempted.

Surgery provides the best chance of a cure and should be used only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall (stage 1). Five-year survival following surgery for stage 1 is 80% (T1/T2, N0, M0). For those with stage 2 it is 30%, stage 3, 18% and stage 4, 4%. Some 70% of patients present with stage ≥ 3 disease, so overall survival is 27% at 1 year and around 10% at 5 years.

Neoadjuvant therapy for potentially resectable squamous carcinomas with cisplatin, 5-fluorouracil and concurrent radiotherapy achieves complete remission in 20–40% with a median survival of 19 months and 25–35% of patients alive 5 years after surgery. There is an increased perioperative mortality. Pre- and postoperative chemotherapy with epirubicin, cisplatin and 5FU for adenocarcinomas at the oesophago-gastric junction has improved overall survival for those patients with resectable disease and good performance status with a relative risk reduction of 25% and absolute improvement in 5-year survival by 13%, from 23% to 36%.

Locally advanced or metastatic disease can be palliated with 5-fluorouracil or capecitabine chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months. Distressing symptomatic problems with dysphagia can be partially relieved by endoscopic insertion of expanding metal stents or percutaneous endoscopic gastrostomy tubes to support liquid enteral feeding and endoscopic ablation to help control bleeding. In deciding upon nutritional measures the patient and their family need considerable support and explanation to understand that feeding including parenteral feeding does not improve survival beyond that dictated by the underlying cancer and may introduce its own complications with adverse effects upon quality of life.

Gastric cancer

Presentation and diagnosis of gastric cancer are described in [Chapter 6](#).

Prognostic factors

The majority of patients are still diagnosed at an advanced stage except in Japan, which has an active surveillance

policy. Thus, in the West, the overall prognosis has not improved above 10% survival at 5 years. Selected groups may do much better and the histological grade and staging with respect to the presence of serosal involvement (T3), nodal involvement (N1–2) and performance status are the main factors in determining prognosis and selecting treatment.

Treatment

Early non-ulcerated mucosal lesions can be removed endoscopically, but suitable lesions are rare outside Japan.

Surgery remains the most effective form of treatment if the patient is operable. Careful selection has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates from 20% to 30%. Five-year survival rates in 'curative' operations are as high as 50%.

Adjuvant treatment trials of perioperative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) improved 5-year survival in operable gastric and lower oesophageal adenocarcinomas from 23% to 36%. Adjuvant postoperative treatment with cisplatin, 5-fluorouracil and radiotherapy compared with surgery alone significantly increased median survival from 28 to 35 months and 3-year survival from 41% to 50%. This was achieved mainly through improvement in loco-regional control but is suitable only for good performance status patients.

Advanced disease may be palliated with chemotherapy such as epirubicin or docetaxel combined with cisplatin and infusional 5-fluorouracil, or oxaliplatin and capecitabine with response in 40–50% of patients for a median of 8–10 months in good performance status patients. The addition of trastuzumab for tumours overexpressing Her2 has improved response as in breast cancer.

Supportive care for patients with upper GI cancers more than any other site must include careful attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes and occasionally parenteral nutrition with the same caveats as above. When the disease progresses beyond active anticancer treatment, management of the distressing obstructive symptoms can be helped with octreotide to reduce secretions and if necessary a venting gastrostomy.

Gastrointestinal stromal tumours (GIST)

These rare slow growing tumours may arise in the stomach, small or large intestine and carry a mutation of the cKit oncogene, which renders them sensitive to the receptor tyrosine kinase inhibitor imatinib (see Ch. 6). Surgery is potentially curative for localized disease and Imatinib can induce remissions in 50–80% by PET-CT criteria for a median of 2 years with further responses to dasatinib.

Lower gastrointestinal

Small intestine cancer

Predisposing factors of small intestine presentation and treatment are described in Chapter 6.

Colorectal cancer

Presentation and diagnosis of colorectal cancer are described in Chapter 6.

Prevention

- Diet. A low-fat, high-fibre diet for the prevention of sporadic colorectal cancer and endoscopic screening is recommended for at-risk patients with a strong family history and for inherited syndromes (e.g. FAP, HNPCC).
- NSAIDs or aspirin may play a role in prevention and after 5 years daily aspirin, there is a 35% reduction in all GI cancers (used for those not at risk of gastric erosions).

Screening

See page 436.

Treatment

Treatment should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery, though fewer than half of these survive more than 5 years. The operative procedure depends on the cancer site. Long-term survival is determined by the stage of the primary tumour, the achievement of clear surgical margins and the presence of metastatic disease (Table 9.33). There has been a gradual move from using Dukes' classification to using the TNM classification system.

Prognostic factors

The site of the disease, above or below the pelvic peritoneal reflection, surgical margins, TNM stage and performance status are the main clinical prognostic factors. Gene profiles are being developed to identify patients at risk of recurrence and who may benefit from adjuvant chemotherapy.

Surgery

- **Rectal cancer.** Total mesorectal excision (TME) is used to carefully remove the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision which requires a permanent colostomy is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Local transanal surgery is very occasionally used for early superficial rectal cancers.
- **Colon cancer.** A segmental resection and restorative anastomosis with removal of the draining lymph nodes

Table 9.33 Staging and survival of colorectal cancers

TNM classification			Modified Dukes' classification	5-year survival (%)
Stage I (N0, M0)	Tumours invade submucosa Tumours invade muscularis propria	T1 T2	A	90
Stage IIA (N0, M0) IIB	Tumours invade into subserosa Tumours invade directly into other organs	T3 T4	B	70 65
Stage III (M0) IIIB IIIC	T1, T2 + 1–3 regional lymph nodes involved T3, T4 + 1–3 regional lymph nodes involved Any T + 4 or more regional lymph nodes	N1 N1 N2	C	60 35 25
Stage IV	Any T, any N + distant metastases	M1	D	7

as far as the root of the mesentery, is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction so surgery can be elective rather than emergency and is probably associated with a decrease in morbidity and mortality.

Adjuvant chemotherapy and radiotherapy

Neoadjuvant chemo-radiation treatment of rectal cancers using cisplatin and 5-fluorouracil with radiotherapy has increased the proportion of locally advanced tumours able to be resected with clear surgical margins (long course radiotherapy) and reduced local relapse rate (both short and long course radiotherapy) but has not improved distant metastatic relapse and overall survival. Preoperative rather than post-operative treatment has reduced toxicity to the other pelvic structures due to the preservation of the normal anatomical relations.

Adjuvant chemotherapy with 6 months of infusional 5-fluorouracil and folinic acid or oral capecitabine for rectal and colonic adenocarcinoma reduces the risk of death by 30% and significantly increases 5-year survival for node-positive disease stage III (Dukes' C) by 10–15%, from 40% to 55%. A further 4% improvement in one trial was achieved by the addition of oxaliplatin but with additional toxicity. Less benefit is seen for stage II node-negative patients. The initial promising results from the addition of biological agents such as bevacizumab have yet to be demonstrated in adjuvant studies and remain experimental.

Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second 'clearance' colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years post-surgery.

Metastatic colorectal cancer

Advanced colorectal cancer is successfully palliated with little toxicity by 5-fluorouracil and folinic acid regimens or oral capecitabine in approximately 30% of patients for a median of 12–14 months. The addition of irinotecan or oxaliplatin increases the proportion who benefit to 55% and extended median survival to 18 months but with increased toxicity. The anti-VEGFR monoclonal antibody bevacizumab and anti-EGFR cetuximab or panitumumab (for those with wild type KRAS and BRAF genes) increase the response rate with chemotherapy to 68% and the median survival from 14 to 24 months.

Liver and lung metastases are a common problem with colorectal cancers. With appropriate selection of patients with a good performance status and in whom MRI and PET-CT scans do not demonstrate extrahepatic disease, local treatment can prolong good quality survival. This can be accomplished with a variety of methods from surgical resection to gamma knife irradiation, radiofrequency, or cryoablation, or hepatic artery embolization. Small lesions can be ablated, larger lesions are best managed by partial hepatectomy or a combination approach so that embolization is followed by hepatic regeneration before final resection. Long-term survival without recurrence is reported in up to 20% of

patients at 5 years with a single <4 cm lesion amenable to resection presenting more than a year from initial diagnosis and may be further extended by perioperative chemotherapy.

Anal cancer

Treatment is, where possible, with surgery or if locally advanced by downstaging with chemoradiotherapy with mitomycin-C (MMC) and 5FU followed by surgery.

Hepatobiliary and pancreatic cancers**Liver****Hepatocellular carcinoma (HCC)****Treatment and prognosis**

HCC arises in a cirrhotic liver in 95% of cases and can be screened and detected by cross-sectional imaging and a rise in serum α -fetoprotein. Surgical resection of isolated lesions <5 cm diameter or up to three lesions <3 cm diameter is associated with a median survival of 5 years although the remaining liver remains at risk of further recurrence. Liver transplantation offers the only opportunity for cure for patients with a small primary but is limited often by the underlying cause of the hepatitis and cirrhosis. Conventional chemotherapy and radiotherapy are unsuccessful, but trans-arterial embolization or radiofrequency ablation in patients with small primaries as above and adequate liver function prolongs survival though less successfully than surgery. Antiangiogenic compounds are being evaluated: sorafenib prolongs survival in patients with non-resectable tumours to 10 months.

Biliary tract cholangiocarcinoma

Cancer of the biliary tree may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified such as that with choledochal cyst and chronic infection of the biliary tree with, for example, *Clonorchis sinensis*. There are also associations with autoimmune disease processes such as primary sclerosing cholangitis.

Cholangiocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is in the early 60s with a ratio of 3 women to 1 man. Gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 1 cm in diameter are also recognized as premalignant lesions.

Carcinoma of the gall bladder is often detected at the time of planned cholecystectomy for gallstones and in such circumstances resection of an early lesion may be curative. Early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions.

Cholangiocarcinoma of the bile ducts usually presents with jaundice and is detected by imaging, initially ultrasound and thereafter CT and in particular magnetic resonance cholangiopancreatography (MRCP). The disease spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach including partial hepatic

resection. Hepatic transplantation for selected stage 1 and 2 disease has achieved 80% 5-year survival.

Palliative chemotherapy for good performance status patients with advanced disease with gemcitabine and cisplatin achieves a response in 50% with a median survival of 12 months. Chemoradiation has been used to treat localized small hilar cholangiocarcinoma and radiotherapy can provide good analgesia.

Pancreas

Pancreatic adenocarcinoma

Prognosis

The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection and a median survival of 2 years but in an elderly population, many of these have co-morbid factors that preclude such major surgery.

Treatment

There is no proven adjuvant therapy for pancreatic cancer following surgery. To optimize the percentage of patients undergoing possible surgical resection it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

In the majority of cases, the management is palliative. Obstruction of the biliary tree and jaundice is a debilitating complication, often associated with severe pruritus but also the cause of nonspecific malaise, lethargy and anorexia. Endoscopic placement of endoprotheses (stents) offers excellent palliation.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases) but in advanced disease self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

Chemoradiotherapy with gemcitabine for small locally advanced disease can achieve response in 30% and a median survival of 17 months. Palliative chemotherapy for advanced disease with gemcitabine and cisplatin can achieve a response in approximately 20% of patients with advanced disease with an improvement in median survival from 6 to 12 months.

With disease progression, abdominal pain is a frequent complicating factor which may prove extremely difficult to treat but can be helped sometimes by radiotherapy.

Neuroendocrine tumours of the pancreas

Treatment options for pancreatic neuroendocrine tumours require a multidisciplinary approach and depend upon the presence or absence of metastatic (usually hepatic) disease. Surgical resection of the pancreatic lesion is the only potential curative approach. Aggressive surgical intervention including a resection of the primary lesion as well as liver resection for metastasis has been used in selected cases. Somatostatin analogues such as octreotide and lanreotide have been used specifically for the control of symptoms secondary to the hormonal secretion. Radionuclide labelled octreotide can also be used to induce responses in 23% for a median of 17 months.

The chemotherapeutic agents streptozotocin, 5-fluorouracil and cisplatin produce partial remission in 33% for a median of 9 months, while median survival was 31 months reflecting their indolent natural history. Sunitinib, the VEGFR inhibitor, can provide palliative benefit with prolongation

of progression-free survival from 5.5 to 11 months and increased survival.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for several years.

Epithelial ovarian cancer

Aetiology and pathology

There is uncertainty over the tissue of origin that gives rise to the 80% of all ovarian cancers that are epithelial (Table 9.34). The ovarian surface epithelium of the serosal peritoneum or the epithelial lining of the fallopian tubes are most likely. There is a consistent relationship between the risk of epithelial ovarian cancer (EOC) and the frequency and duration of ovulation. While not mechanistically explained this has provided a successful rationale for reducing risk of EOC by up to one-third through early pregnancy and the use of the oral contraceptive pill. The non-epithelial cancers are of germ cell or stromal origin although molecular biological markers have shown that the category of mixed Müllerian sarcoma is an entirely epithelial tumour with metaplastic stromal elements.

Symptoms and signs

Ovarian cancer typically causes few specific symptoms, often leading to late diagnosis. However, the following are most often associated and need investigation:

- Persistent abdominal distension (women often refer to this as bloating)
- Feeling full when eating or early satiety and loss of appetite
- Pelvic or abdominal pain
- Increased urinary urgency or frequency.

Sometimes, there is a sensation of a pelvic mass, which may become (acutely) painful, often there is only vague abdominal distension and epigastric discomfort. Symptoms of irritable bowel syndrome can be confused with those of ovarian cancer but rarely present for the first time over the age of 50 when they should stimulate investigation for ovarian cancer.

On examination, the majority of patients present with a pelvic mass and advanced stage III (spread within the peritoneal cavity) or IV (extraperitoneal) disease. Screening (see p. 436) by serum CA125 tumour marker and transvaginal ultrasound scan does detect some early cancers with improved survival but is being further refined with serial tests to avoid

too many negative laparotomies and is thus still considered a research tool.

Investigation

Pelvic examination should be complemented by a serum CA125 tumour marker in primary care and transvaginal ultrasound. MRI is the definitive imaging technique for the pelvis while CT-PET scans assist in staging the patient.

An RMI >250 (risk of malignancy index, [Table 9.35](#)) should trigger investigation by a specialist gynaecological cancer team.

Prognostic factors

Histological subtype (clear cell and mucinous are worse), grade/differentiation, stage, extent of residual disease following surgery (macroscopic versus microscopic or none) and performance status are all significant independent prognostic factors for survival ([Table 9.36](#)).

Treatment

Surgery (with total abdominal hysterectomy, bilateral salpingo-oophorectomy and omentectomy) has a major role in the treatment of ovarian cancer. For patients in whom the disease is confined to the ovary, i.e. stage I, the surgery can be curative in 80–90% if the histology is well to moderately differentiated. For patients with poorly differentiated or more advanced disease, with spread throughout the peritoneal cavity, surgery still has a major role in staging the patient and improving survival when it is possible to debulk optimally to no visible residual disease. Primary chemotherapy and delayed surgery is an alternative approach when the disease is too advanced to permit primary debulking surgery and is able to render approximately one-third of inoperable patients fit for optimal debulking surgery. Survival of patients with

such advanced disease is equal whether chemotherapy is given before or after surgery but preoperative downstaging can avoid much surgical morbidity.

Carboplatin, which is associated with fewer side-effects than cisplatin, has become the mainstay of epithelial ovarian cancer chemotherapy. Response is achieved in approximately two-thirds of patients. Paclitaxel has been shown to increase the response rate and improve the survival of many patients when added to a platinum-based treatment.

Adjuvant treatment with carboplatin and paclitaxel for stage I high-risk disease increases the absolute 5-year survival by 9%, from 70% to 79% and for combined stages I–III completely debulked disease by 19%, from 60% to 79%, a relative risk reduction of 29%.

In more advanced disease, 75% of patients will respond to combination chemotherapy and the median survival is approximately 3 years. Treatment at recurrence can be delayed until the disease is symptomatic. Further palliative responses can be achieved with carboplatin and paclitaxel if the treatment-free interval is >6 months, or liposomal doxorubicin, etoposide, gemcitabine and trabectedin are all active drugs for the palliation of recurrent disease. Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if the cancer is not able to be debulked at operation or has spread outside the peritoneal cavity. It has proven difficult to develop more targeted biological agents for ovarian cancer. Bevacizumab when added to chemotherapy has increased disease-free survival by a few months and BRCA-positive tumours are sensitive to PARP inhibitors such as olaparib.

Epithelial ovarian cancer tends to remain within the peritoneal cavity often exclusively which has led to new intra-peritoneal routes of administration of treatment with potentially improved survival. However, at recurrence bulk disease in the peritoneum commonly causes progressive bowel obstruction which may require palliative operation or expert palliative care support to manage the terminal phases of the illness.

Urological cancers**Renal cell carcinoma****Presentation and diagnosis**

See [Chapter 12](#).

Investigation and treatment

At diagnosis, renal cancers are staged using CT and/or MRI scans to assess operability and the presence of distant metastases. Prognosis depends upon the TNM stage, histological subtype and grade, performance status and serum LDH, calcium and haemoglobin levels.

A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted when the primary tumour constitutes the main bulk of disease since regression of metastases has been reported after removal of the main tumour mass. Adjuvant treatments are unproven and being investigated. The 5-year survival rate is 60–70% with tumours confined to the renal parenchyma, 15–35% with lymph node involvement and only approximately 5% in those who have distant metastases.

Metastatic disease

Metastases are present in 20–30% of patients at diagnosis and are likely to develop in 40% of patients following surgery

Table 9.35 Risk of ovarian malignancy index (RMI)

RMI combines three pre-surgical features: serum CA125 (CA125), menopausal status (M) and ultrasound score (U). The RMI is a product of the ultrasound scan score, the menopausal status and the serum CA125 level (IU/mL). $RMI = U \times M \times CA125$ and if >250 is strongly suspicious for ovarian cancer.

The ultrasound result is scored 1 point for each of the following characteristics: multilocular cysts, solid areas, metastases, ascites and bilateral lesions. U = 0 (for an ultrasound score of 0), U = 1 (for an ultrasound score of 1), U = 3 (for an ultrasound score of 2–5).

The menopausal status is scored as 1 = premenopausal and 3 = postmenopausal.

The classification of 'postmenopausal' is women who have had no period for more than one year or women over the age of 50 who have had a hysterectomy.

Serum CA125 is measured in IU/mL and can vary between 0 to hundreds or even thousands of units.

Table 9.36 Invasive epithelial ovarian cancer

Stage	Relative 5-year survival rate	Stage	Relative 5-year survival rate
I	89%	IIC	57%
IA	94%	III	34%
IB	91%	IIIA	45%
IC	80%	IIIB	39%
II	66%	IIIC	35%

for apparently localized disease. Prognosis without treatment depends upon the extent of the disease as measured by the Memorial Sloan-Kettering Cancer Center (MSKCC) index comprising: performance status, high LDH, low haemoglobin, high calcium and primary *in situ*. Patients with no metastases and a score of 0 have a median survival of 20 months, those with a score of 1–2 have median survival 10 months and those with a score of >2 have median survival of 4 months.

Immunotherapy for renal cancer has been pursued since the observation of the occasional regression of metastases either spontaneously or following nephrectomy. In good performance status patients interferon- α produces a response in 16% with a median survival of 15 months. Interleukin-2 and interferon with 5FU is associated with a higher response rate (23%) but no longer survival. Other approaches such as tumour cell vaccines and stem cell transplants continue to be investigated.

Agents that target the VEGF (and other) receptors have been investigated because the inactivation of the VHL pathway in renal cancers leads to an increase in VEGF and PDGF production which is inversely associated with prognosis. The tyrosine kinase inhibitors sunitinib and sorafenib, the monoclonal antibody bevacizumab and the mTOR inhibitor temsirolimus have all demonstrated an ability to delay progression of disease and temsirolimus an improvement in survival. However, the incidence of cardiovascular and cerebrovascular toxicity may limit their use.

Urothelial cancers

Presentation and diagnosis

Prognosis depends upon the performance status of the patient, the TNM stage of the tumour (in particular in the bladder whether it has penetrated the bladder muscle) and its degree of differentiation. After surgery, the surgical margins, lymphovascular invasion and nodal involvement are further prognostic factors.

Treatment

Renal pelvis and ureteric tumours

Early stage tumours are treated by nephroureterectomy. Adjuvant radiotherapy and chemotherapy appear to be of little or no value. The remainder of the urothelium is at risk of further primary transitional cell cancers (TCC) in about half the patients and requires surveillance cystoscopy. Metastatic TCC is treated as for bladder below.

Bladder tumours

Superficial bladder TCC within the basement membrane are treated by transurethral resection or local diathermy. The risk of recurrence varies with the differentiation and follow-up check cystoscopies and cytological examination of the urine are required. Recurrent superficial TCC can be treated with bladder instillation of BCG (bacille Calmette-Guérin) or alternatively with chemotherapy agents such as doxorubicin, or mitomycin to delay further recurrence for on average 18 months.

Patients with muscle invasive bladder tumours are treated with radical cystectomy in patients under 70 years and radical radiotherapy in those over 70 years with salvage cystectomy for recurrences. The prognosis ranges from a 5-year survival rate of 80–90% for lesions not involving bladder muscle to 5% for those presenting with metastases.

Alternatively, those with T1 grade 3 to T4 tumours can be offered the chance of bladder preservation with chemoradiotherapy with cisplatin and 5FU. This can achieve complete response at subsequent transurethral resection in

66%, bladder preservation and a good quality of life in 67% and a comparable long-term survival (30–50% 5 years) to cystectomy. Cystectomy requires a new bladder to be made out of small bowel, joining this to the urethra if possible, or an ileal conduit.

Prostate cancer

Early prostate cancer

Presentation and diagnosis are described on [page 635](#).

Prognostic factors

Diagnosis is usually made on a raised serum PSA (prostate-specific antigen) followed by a transrectal ultrasound-guided needle biopsy. The histological appearances are graded and accorded a Gleason Score, which together with the height of the serum PSA plus accurate staging of the local extent of disease with pelvic MRI and transrectal ultrasound can identify prognostic groups ([Table 9.37](#)). Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer, which is becoming more objectively identifiable with advances in gene profiling. This allows the selection of patients with good prognosis for no active treatment who may reasonably choose to be kept under surveillance and, like 75% of men over the age of 80, die with, but not because of, their prostate cancer.

Treatment ([Chapter 12](#))

Patients with disease localized to the prostate requiring treatment can be managed by curative surgery (radical prostatectomy), or external beam radiotherapy, or brachytherapy implants which can achieve equivalent survival rates but differ in the spectrum of unwanted side-effects with respect to incontinence and sexual dysfunction. Radiotherapy tends to be more used in older patients who wish to avoid surgery. In appropriately selected series of patients a 5-year survival of 85% can be achieved. Adjuvant radiotherapy after radical prostatectomy can reduce PSA relapse but has not increased overall survival. Discussion between patient and clinician is vital to enable a treatment choice that is most appropriate to the patient's circumstances; many of the patients are elderly and the side-effects of treatment are significant with often no improvement in mortality.

Androgen deprivation

- GnRH agonists, e.g. goserelin and leuprorelin, and orchidectomy are equally effective in lowering circulating androgens and inducing responses in prostate cancer. However, in the first week GnRH agonists produce a rise in LH and testosterone which can result in a tumour flare in metastatic disease and require combination with an antiandrogen, e.g. flutamide, in the initial phases.

- Androgen receptor blockers such as flutamide and abiraterone, an inhibitor of CYP17 which is necessary for androgen production, are also effective and abiraterone has been effective after failure of androgen suppression.

Adjuvant androgen deprivation treatment such as monthly depot goserelin has not improved the survival following surgery but when given before and during radiotherapy can improve the overall survival at 3 years for T1–T3 tumours from 62% to 78%.

Advanced prostate cancer

Treatment

Locally advanced prostate cancer (T3 N0) without distant metastases is best treated with combined androgen deprivation and radiotherapy, which improves 10-year survival compared with endocrine treatment alone from 61% to 71%.

Metastatic prostate cancer with either local or most often osteoblastic skeletal spread, is rapidly and effectively palliated in 70% of patients by androgen deprivation through orchidectomy, monthly depot injection of GnRH analogues goserelin or leuporelin, or androgen receptor blockade with oral flutamide. The median duration of response is 2 years. However, on progression despite androgen suppression, prostate cancer management must be further tailored to the patient's age, performance status and bone marrow function. These measures include simple steroids and bisphosphonates, or docetaxel chemotherapy which can be guided by PSA response to provide some further palliation. Abiraterone is an inhibitor of adrenal androgen synthesis which has achieved responses in 50% of castration-resistant post docetaxel patients for a median duration of 6 months. Radiotherapy provides very effective palliation for the common problem of painful skeletal metastases and can be delivered by external beam therapy or systemically by intravenous bone-seeking strontium-labelled bisphosphonate for patients with multiple affected sites.

Bone pain can also be reduced with bisphosphonates such as zoledronate, as the metastatic sites comprise a combination of increased osteoclastic and osteoblastic activity.

Testicular and ovarian germ cell tumours

Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types, seminoma (dysgerminoma in women) and teratoma. Teratomas may comprise varying proportions of mature and immature elements. Mature teratomas in women present as dermoid cysts with low malignant potential. Germ cell tumours may rarely occur in extragonadal sites in the midline from pituitary, mediastinum or retroperitoneum but should be treated in a similar manner (Table 9.38).

Symptoms and signs

Most men present with a testicular mass which is often painful, some with symptoms of metastases to the

para-aortic lymph nodes with back pain and gynaecomastia if hCG secreting. In women, the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers.

Investigations and surgery

- Ultrasound or MRI scanning of the testicle or ovary is required.
- Assay of serum tumour markers, α -fetoprotein (AFP) and beta-human chorionic gonadotrophin (β -hCG) and lactic dehydrogenase (LDH).

A urinary pregnancy test for hCG in A&E has saved the lives of young men with metastatic germ cell cancer.

- CT or MRI scan for distant metastases.
- Surgery for men is by the inguinal approach to avoid spillage of highly metastatic tumour in the scrotum.
- Surgery in women for diagnosis and staging should always be conservative compared to the approach in epithelial ovarian cancer with preservation of fertility because of the efficacy of chemotherapy.

Treatment

Seminomas

Seminomas are the least common of these tumours and are very radiosensitive and chemosensitive. Seminomas are associated with a raised serum LDH but only rarely a mildly raised β -hCG and never a raised AFP. Stage I disease limited to the gonad is associated with a 30% 5-year risk of recurrence with surgery alone. Adjuvant therapy with either chemotherapy or radiotherapy to the para-aortic lymph nodes leads to greater than 95% cure in early-stage disease but chemotherapy with single-agent cisplatin or carboplatin does not have the long-term risks of secondary malignancy associated with radiotherapy. Alternatively, intensive surveillance can be undertaken with treatment reserved for those who relapse with an equally high cure rate since combination chemotherapy (e.g. cisplatin, etoposide and bleomycin) will cure 90% of those with visible metastatic disease.

Teratomas

The risk of relapse with stage I disease varies from 5% to 40% depending upon the prognostic factors of histological differentiation and extent of local invasion.

Adjuvant chemotherapy for those at moderate to high risk with cisplatin, etoposide and bleomycin leads to a 95% cure rate. In those without vascular invasion a single cycle of treatment can be given instead of retroperitoneal lymph node dissection.

Metastatic disease commonly involves para-aortic lymph nodes and lungs but may spread rapidly (especially if there are trophoblastic (β -hCG-producing) elements present) and cause life-threatening respiratory or other organ failure. A rapid diagnosis can be made in the presence of gynaecomastia and a positive urinary pregnancy test before the institution of potentially life-saving treatment. About 80% of teratomas will express either β -hCG or AFP and almost all metastatic disease will be associated with an elevation of the less-specific serum marker LDH.

Chemotherapy cure for metastatic teratoma varies from over 90% for those with small-volume to 40% for those with large-volume metastases and associated rises of AFP >10000 and β -hCG >100000 IU/L.

Although approximately 20% of men will be infertile due to azoospermia at the time of diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father normal children. Similarly, most women retain

Table 9.38 Germ cell histology: WHO classification

Seminoma

Teratoma mature, immature, or with malignant differentiation
Choriocarcinoma
Endodermal sinus tumour
Mixed teratoma

their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

Metastatic cancer of unknown primary

Patients presenting with symptoms of their metastases or with an incidental finding on imaging without a clinically obvious primary after investigation represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. As a result of several systematic studies, some with post-mortem follow-up, the following guidance should aid the choice of appropriate investigation and treatment. Poor prognosis patients identified by performance status, histology, site and extent of disease on the other hand can be spared the discomfort of intensive investigation and given more appropriate palliative care.

Diagnosis

Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

- **Squamous cancers:** mostly presenting in the lymph nodes of the cervical region, 80% will be associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes point usually to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential especially in the head and neck area even in the absence of an identifiable primary on pan-endoscopy.
- **Poorly differentiated or anaplastic cancers:** this group will contain the majority of the curable cancers such as high-grade lymphomas and germ cell tumours and should be suspected in all young patients with midline masses. They are identifiable by their immunocytochemistry and tumour markers. Gene markers such as ip12 for germ cell tumours and Bcl-2 for lymphomas are increasingly available to aid this diagnosis. Treatment and prognosis are as outlined for lymphoma and germ cell tumours.
- **Adenocarcinomas** form the majority of cases and their investigation should be guided by the desire to identify the most treatable options and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects.

Tissue tumour markers can be helpful (Table 9.39) and increasingly, gene profiles can identify the primary site of origin by gene expression microarray and RT-PCR.

Investigations should therefore always start with a review of the histology, a chest X-ray and CT scan of chest, abdomen and pelvis, with, in men, serum PSA and rectal ultrasound to identify prostate cancers and in women, mammography and breast MRI to identify occult breast cancer and pelvic MRI to identify ovarian cancer.

For good prognosis patients wishing to have palliative chemotherapy, investigations such as endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents, although the diagnostic yield of 4–5% must be set against the discomfort and risks. Serum tumour markers for other solid cancers, although highly sensitive, are too nonspecific and unreliable to be useful as diagnostic aids in this situation.

Further investigation may require PET-CT for head and neck, lung and possibly other primaries and radioisotope scans for thyroid and carcinoid tumours. PET-CT may also be used to seek other metastatic sites if considering surgery for unifocal disease.

Table 9.39 Adenocarcinoma of unknown primary (ACUP): immunohistochemistry markers of most probable but not exclusive tissue of origin

Immunohistochemistry markers	Probable tissue of origin
EMA (epithelial membrane antigen)	Epithelial
LCA (leucocyte common antigen)	Lymphoid
Cytokeratin 7+ 20+	Pancreas 65%, cholangiocarcinoma 65% Gastric 40%, transitional cell 65%, ovarian mucinous 90%
Cytokeratin 7+ 20–	Ovarian (except mucinous) 100%, breast 90%, lung adeno 90%, uterus endometrioid 85%, transitional cell 35%, pancreas adeno 30%, cholangiocarcinoma 30%, thyroid 100%, mesothelioma 65%
Cytokeratin 7– 20+	Colorectal adeno 80%, gastric adeno 35%, Merkel cell 70%
Cytokeratin 7– 20–	Hepatocellular 80%, carcinoid 80%, lung small cell and squamous 75%, prostate 85%, renal adeno 80%, adrenal 100%, germ cell 95%, squamous cancer of head and neck and oesophagus 70% mesothelioma 35%
TTF-1 (thyroid transcription factor)	Lung and thyroid cancer
Thyroglobulin	Thyroid cancer
ER and PR and Her2 receptors	Breast cancer
PSA	Prostate and breast cancer
CEA (carcinoembryonic antigen)	Gastrointestinal cancer
CDX2	Colorectal and small intestinal
Villin	Gastrointestinal
CA125 peritoneal antigen	Ovarian, fallopian tube and primary peritoneal and breast cancer
WT1	Ovarian serous cancer, mesothelioma, desmoplastic tumours, Wilms' tumours
S100, melanin and HMB45	Melanoma
Myosin, desmin and factor VIII	Soft tissue sarcoma
Chromogranin and NSE (neurone specific enolase)	Neuroendocrine cancers
AFP (α -fetoprotein)	Germ cell tumours and hepatocellular carcinoma
β -hCG (beta human chorionic gonadotrophin)	Germ cell and trophoblastic tumours
CD117	Gastrointestinal stromal tumours

Prognosis

The histological type and extent of the disease and performance status of the patient are the key factors. Most large series report an overall median survival of 12 weeks but considerably better survival amongst the special subgroups such as patients presenting with isolated nodal metastases who have a significantly better prognosis than the majority with visceral and/or bone metastases and may warrant more extensive investigation.

Treatment

If investigations have not identified a primary site, surgery may be considered for unifocal ACUP metastases in lymph nodes, lung, liver and brain especially if due to melanoma with potential for long-term survival.

In women, an isolated axillary lymph node metastasis should be treated as for lymph-node-positive breast cancer with a similar prospect for long-term cure though without the need for breast surgery. Malignant ascites in women should have a trial of chemotherapy as for primary peritoneal, fallopian tube or epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to the disease of known primary origin. Primary chemotherapy that achieves an excellent response by imaging and CA125

**Box 9.14 Adenocarcinoma with unknown primary: primary sites with major treatment benefits**

- Breast, e.g. isolated axillary lymphadenopathy
- Ovary, e.g. peritoneal carcinomatosis
- Prostate, e.g. pelvic lymphadenopathy

criteria should be followed by debulking surgery with, if successful, a median survival in excess of 4 years.

For men, the occasional occult prostatic cancer found from a raised serum PSA offers some palliative treatment prospects (Box 9.14).

For the patient presenting with hepatic metastases most commonly associated with an occult gastrointestinal primary there is an increasing choice and efficacy of chemotherapy agents for gastrointestinal cancers that have the potential to improve their palliation.

If there is an excellent response, suitable patients may even be considered for hepatic ablation or resection. If after all efforts no primary has been identified, palliative chemotherapy treatment can achieve responses in 20–40% in highly selected series, with median survivals of 9–10 months and 5–10% surviving to 5 years.

Palliative medicine and symptom control

Introduction and general aspects
Symptom control

485
485

Extending palliative care to people with non-malignant disease

490

INTRODUCTION AND GENERAL ASPECTS

Palliative care is the active total care of patients who have advanced, progressive life-shortening disease. It is now recognized that palliative care should be based on needs not diagnosis: it is needed in many non-malignant diseases as well as in cancer (Box 10.1).

The goal of palliative care is to achieve the best possible quality of life for patients and their carers by managing not only physical symptoms, but also psychological, social and spiritual problems. When life-prolonging treatments are no longer improving or maintaining quality of life, death is accepted as a normal process. The aim is to enable the patient to be cared for and to die in the place of their choice, with excellent symptom control and an opportunity to say goodbye and bring closure.

Who provides palliative care?

A hallmark of palliative care is the multiprofessional team, as single professionals cannot provide the breadth of necessary expertise, and the emotional demands of working in this area require team support to enable balanced, compassionate but dispassionate care.

All healthcare providers should have basic palliative care skills and access to a specialist palliative care (SPC) team. They should be aware of the services that the local SPC teams can offer and recognize when referral is appropriate. A problem-based approach to disease management will ensure that patients and carers obtain access to appropriate support services, including SPC and will avoid an either/or approach ('either curative treatment or palliative care').

Good communication between members of the healthcare team, and the patient and carer underpins the successful management of advanced disease and end-of-life care. Good liaison between the hospital, primary care and hospice is also essential.

Importance of early assessment

Early assessment of needs, with SPC referral if required, is crucial to obtaining the best outcome for rehabilitation and for maintaining or improving quality of life for both patient and carer. Palliative care is most effective when it is given as

soon as possible after diagnosis and is given alongside disease-specific therapy, such as radio/chemotherapy for cancer or cardiac medication for heart failure. Early referral links palliative care with quality of life improvements; positive associations increase the likelihood that patients and families continue to use palliative care services when they need them. Furthermore, in malignant disease, there is good evidence that integrating palliative care and anti-tumour treatment soon after diagnosis reduces long-term distress and increases survival in selected cases.

If palliative care is seen only as relevant for the end-of-life phase, patients who have non-malignant disease are denied expert help for complex symptoms. Timely management of physical and psychosocial issues earlier in the course of disease prevents intractable problems later (Box 10.2).

Assessment of patient's needs and understanding

The causes of a patient's symptoms are often multifactorial, and a holistic assessment is central to optimum management. Assessment of the patient's understanding of the disease, understanding their future wishes and acknowledging their concerns, will help the team plan and implement effective support. Patients will have differing needs for information, and will deal with 'bad news' in different ways. A sensitive approach, respecting individual requirements, is crucial.

Recent changes in provision of palliative care

An increase in the number of patients who survive malignant disease and a recognition of the needs of patients who have non-malignant disease have led to changes in the provision of SPC services. Many patients will use SPC services for a limited period (weeks to months) whilst complex problems are addressed, and then are discharged with the opportunity for re-referral if help is required later.

SYMPTOM CONTROL

This section outlines the medical aspects of symptom control. Good palliative care integrates these with appropriate non-pharmacological approaches, including anxiety management and rehabilitation (see p. 489).

FURTHER READING

Temel JS, Greer JA, Muzikansky A et al. Early palliative care for patients with metastatic non-small-cell lung cancer. *N Engl J Med* 2010; 363(8): 733–742.

Box 10.1 Key components of a modern palliative care service

- Management should be based on *needs* not diagnosis: the symptom burden of non-malignant disease often equals that of cancer
- Care should be independent of the patients' location and should help patients to remain at home if possible, avoiding unwanted admissions to hospital
- Rehabilitation for people with advanced disease
- Support for carers
- Bereavement care for people with pathological grief problems
- Telephone advice for other clinicians; disseminating palliative care knowledge
- Teaching for clinicians, from undergraduate level to postgraduate life-long learning

Box 10.2 Problems arising when specialist palliative care (SPC) is delayed until the end-of-life

- There is insufficient time to achieve good symptom control by combining non-pharmacological and pharmacological components
- SPC services are deemed less acceptable by patient and family, being associated with 'dying' or 'giving up' or 'giving in' to illness
- Psychological distress and physical symptoms become intractable and contribute to complex grief
- It becomes too late to adopt rehabilitative approach or teach/use non-pharmacological interventions that need a degree of training and patient motivation (e.g. cognitive behavioural approaches, mindfulness meditation, attendance at day therapy)

Pain

Pain is a feared symptom in cancer and at least two-thirds of people with cancer suffer significant pain. Pain has a number of causes, and not all pains respond equally well to opioid analgesics (Fig. 10.1). The pain is either related directly to the tumour (e.g. pressure on a nerve) or indirectly, for example due to weight loss or pressure sores. It may result from a co-morbidity such as arthritis. Emotional and spiritual distress may be expressed as physical pain (termed 'opioid irrelevant pain') or will exacerbate physical pain.

The term 'total pain' encompasses a variety of influences that contribute to pain:

- **Biological:** the cancer itself, cancer therapy (drugs, surgery, radiotherapy)
- **Social:** family distress, loss of independence, financial problems from job loss
- **Psychological:** fear of dying, pain, or being in hospital; anger at dying or at the process of diagnosis and delays; depression from all of above
- **Spiritual:** fear of death, questions about life's meaning, guilt.

The WHO analgesic ladder

Most cancer pain can be managed with oral or commonly used transdermal preparations. The World Health Organization (WHO) cancer pain relief ladder guides the choice of analgesic according to pain severity (Fig. 10.2, Table 10.1).

If *regular* use of optimum dosing (e.g. paracetamol 1 g×4 daily for step 1) does not control the pain, then an analgesic from the next step of the ladder is prescribed. As pain is due to different physical aetiologies, an adjuvant analgesic may

Figure 10.1 Management of cancer pain.

Table 10.1 Commonly used adjuvant analgesics

Drugs	Indication
NSAIDs, e.g. diclofenac	Bone pain, inflammatory pain
Anticonvulsants, e.g. gabapentin (600–2400 mg daily) or pregabalin (150 mg at start increasing up to 600 mg daily)	Neuropathic pain
Tricyclic antidepressants, e.g. amitriptyline (10–75 mg daily)	Neuropathic pain
Bisphosphonates, e.g. disodium pamidronate	Metastatic bone disease
Dexamethasone	Neuropathic pain, inflammatory pain (e.g. liver capsule pain), headache from cerebral oedema due to brain tumour

be needed in addition or instead, such as the tricyclic antidepressant amitriptyline for neuropathic pain (Table 10.1).

Strong opioid drugs

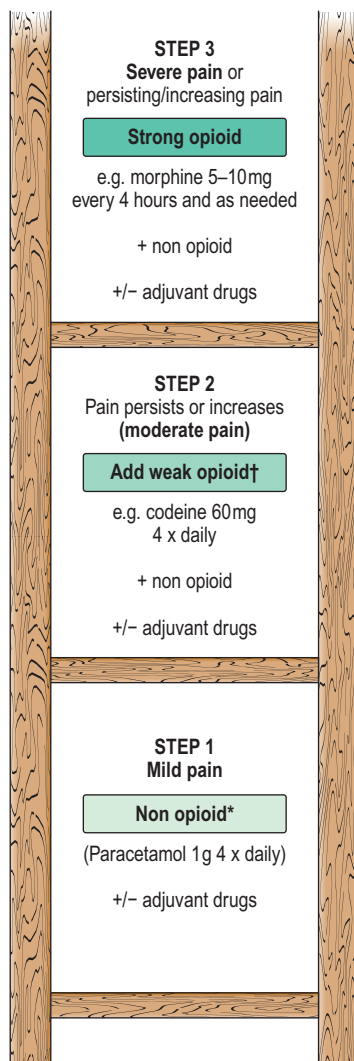

Dose titration and route

Morphine is the drug of choice and, in most circumstances, should be given regularly by mouth. The dose should be tailored to the individual's needs by allowing 'as required' doses; morphine does not have a 'ceiling' effect. If a patient has needed further doses in addition to the regular daily dose, then the amount in the additional doses can be added to the following day's regular dose until the daily requirement becomes stable; a process called 'titration'. When the stable daily dose requirement has been established, the morphine can be changed to a sustained-release preparation. For example:

20 mg morphine elixir 4-hourly
 = 120 mg morphine per day
 = 60 mg twice-daily of a 12-hour preparation
 or 120 mg daily of a 24-hour preparation.

FURTHER READING

SIGN. Control of Pain in Adults with Cancer. Publication No. 106. Edinburgh: SIGN; 2008; <http://www.sign.ac.uk/pdf/SIGN106.pdf>.

Adjuvant drugs (Table 10.1) are used:

- To counter adverse effects
- As psychotropic medication
- As analgesics in their own right

Figure 10.2 WHO analgesic ladder for cancer and other chronic pain. Step 2 can be omitted, going to morphine immediately. Adjuvant drugs are listed in Table 10.1.

*Opioids include all drugs with an action similar to morphine, i.e. binding to endogenous opioid receptors. †Continue NSAID/paracetamol regularly when opioid started.

The starting dose of morphine is usually 5–10 mg every 4 hours, depending on patient size, renal function and whether they are already taking a weak opioid.

If there is significant renal dysfunction, morphine should be used in low doses and should not be given in continuous dose regimens (e.g. by subcutaneous infusions) because of the risk of metabolite accumulation (it is renally excreted). In renal impairment, an alternative opioid (e.g. fentanyl) can be given transdermally, e.g. 72-hour self-adhesive patches.

If a patient is unable to take oral medication due to weakness, swallowing difficulties or nausea and vomiting, the opioid should be given parenterally. For cancer patients who are likely to need continuous analgesia, continuous subcutaneous infusion is the preferred route.

Both doctors and patients may have erroneous beliefs (e.g. fear of addiction), which mean that adequate doses of

opioids are not prescribed or taken; however, addiction is very rare with the risk of iatrogenic addiction being <0.01%.

Side-effects

The most common side-effects are:

- **Nausea and vomiting:** this can usually be managed or prevented with antiemetics (such as metoclopramide). Some antiemetics can be combined with an opioid, e.g. haloperidol or metoclopramide; always check compatibility data.
- **Constipation** is common and should be anticipated with administration of a combination of stool softener (e.g. macrogols) and stimulants either separately or in one preparation Methyl naltrexone is a peripherally acting opioid receptor antagonist which is used if response to other laxatives is poor.

If side-effects are intractable, a change of opioid is often helpful.

Toxicity

Confusion, persistent and undue *drowsiness*, *myoclonus*, *nightmares* and *hallucinations* indicate opioid toxicity. This may follow rapid dose escalation and responds to dose reduction and slower re-titration. It may indicate poorly opioid responsive pain and the need for adjuvant analgesics.

Antipsychotics such as haloperidol may help settle the patient's distress whilst waiting for resolution of toxicity. Some patients will tolerate an alternative opioid better, e.g. oxycodone, or, an alternative route, e.g. subcutaneous injection.

Adjuvant analgesics

The most commonly used adjuvant analgesics are described in Table 10.1. Other treatments such as radio/chemotherapy, anaesthetic or neurosurgical interventions, acupuncture and TENS may be useful in selected patients.

Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from pain distress.

Gastrointestinal symptoms

Anorexia, weight loss, malaise and weakness

These result from the cancer-cachexia syndrome of advanced disease and carry a poor prognosis. Although attention to nutrition is necessary, the syndrome is mediated through chronic stimulation of the acute phase response, and tumour-secreted substances (e.g. lipid mobilizing factor and proteolysis inducing factor). Thus, calorie-protein support alone gives limited benefit: parenteral feeding has been shown to make no difference to patient survival or quality of life.

There is a small and evolving evidence base for specific therapies such as eicosapentaenoic acid (EPA) fish oil, cyclooxygenase (COX) inhibition with an NSAID and antioxidant treatment, but currently, unless the patient is fit enough for, and responds to, anti-tumour therapy, management is supportive. Some patients benefit from a trial of a food supplement that contains EPA and antioxidants. Megestrol may help appetite, but weight gain is usually fluid or fat. It is also thrombogenic and is of little benefit.

Until recently, corticosteroids were recommended and they are still commonly used as an appetite stimulant; however, the weight gained is usually fluid and muscle catabolism is accelerated. Also, any benefit in appetite stimulation tends to be short-lived. Thus, their use should be limited to short term only.

Using a hand-held fan to alleviate breathlessness. For more on interventions for breathlessness, see <http://www.cuh.org.uk/breathlessness>.

FURTHER READING

Laval G, Girardier J, Lassauniere JM et al. The use of steroids in the management of inoperable intestinal obstruction in terminal cancer patients: do they remove the obstruction? *Palliat Med* 2000; 14(1):3–10.

Nausea and vomiting

Nausea and vomiting is common, and often due to use of opioids without antiemetics such as haloperidol 1.5 mg×1–2 daily or metoclopramide 10–20 mg×3 daily. When nausea and vomiting are associated with chemotherapy, patients should have an antiemetic, starting with metoclopramide or domperidone, but if the risk of nausea and vomiting is high, give a specific 5HT₃ antagonist, e.g. ondansetron 8 mg orally or by slow i.v. injection.

For most chemical causes, e.g. hypercalcaemia, haloperidol 1.5–3 mg daily is the first choice. Metoclopramide is also a prokinetic and therefore useful for emesis due to gastric stasis or constipation. Cyclizine 50 mg×3 daily is also used.

For any cause of vomiting, it may be necessary to start antiemetic therapy parenterally by continuous subcutaneous infusion to gain control. If the patient has gastrointestinal obstruction, this route may need to be continued.

Gastric distension

Gastric distension due to pressure on the stomach by the tumour (squashed stomach syndrome) is treated with a prokinetic, e.g. domperidone 10 mg×3 daily.

Bowel obstruction

Metoclopramide should be avoided in complete bowel obstruction where an antispasmodic such as hyoscine butylbromide (60–120 mg/24 hours s.c.) is preferred. Control of vomiting in bowel obstruction may also need the addition of octreotide (a somatostatin analogue) to reduce gut secretions and volume of vomitus, or physical measures such as defunctioning colostomy or a venting gastrostomy. Occasionally, a lower bowel obstruction is resolved with insertion of a stent, or transrectal resection of tumour. Steroids shorten the length of episodes of obstruction, if resolution is possible.

In advanced disease, the patient should be encouraged to drink and take small amounts of soft diet as they wish. With good mouth care, the sensation of thirst is often avoidable, thus sometimes preventing the need for parenteral fluids.

Respiratory symptoms**Breathlessness**

Breathlessness remains one of the most distressing and common symptoms in palliative care; causing the patient serious discomfort, it is highly distressing for carers to witness. Full assessment and active treatment of all reversible conditions, such as drainage of pleural effusions, or optimization of treatment of heart failure or chronic pulmonary disease is mandatory. In advanced cancer, breathlessness is often multifactorial in origin and many of the contributory factors are irreversible (e.g. cachexia), so a 'complex intervention' combining a number of different treatment strategies has the greatest impact. Aspects of breathlessness management are summarized in **Box 10.3**.

Breathlessness with panic and anxiety

Patients often experience a panic-breathlessness cycle and fear dying during an acute episode of breathlessness. This is extremely unlikely in chronic disease, unless there is an acute complication, and reassurance will help. The perception of breathlessness is mediated by the central nervous system and can be modulated by thoughts and feelings about the sensation. Education about breathlessness and exploration

**Box 10.3 Key points for successful management of breathlessness**

- **Start treatment early:** patients who are likely to develop breathlessness should learn non-pharmacological approaches early in the disease course, before breathlessness has become severe.
- **Involve the carer in the treatment strategy:** watching breathlessness episodes and being unable to help is a terrifying experience (and promotes the panic-anxiety cycle); if patients and carers develop a joint ritual for crises, chronic anxiety can be reduced.
- **Ensure management is rehabilitative** (see p. 489): this increases physical fitness, hope, self-efficacy, and may enable patient and carer to achieve goals that once seemed impossible.
- **Integrate psychological, physical and social interventions**, as with all palliative care.

of psychological precipitators or maintainers can reduce its impact.

Non-pharmacological approaches such as using a hand-held fan, pacing, prioritizing activities to avoid over-exertion, breathing training and anxiety management are helpful (**Table 10.2**). There is no evidence to suggest that oxygen therapy reduces the sensation of breathlessness in advanced disease and the hand-held fan should be used before oxygen for this purpose. Opioids, used orally or parenterally, can palliate breathlessness. If panic/anxiety is significant, a quick-acting benzodiazepine such as lorazepam (used sublingually for rapid absorption) may be useful.

Cough

Persistent unproductive cough is another troublesome symptom that can be helped by the antitussive effect of opioids (e.g. morphine). Excessive respiratory secretions can be treated with hyoscine hydrobromide 400–600 µg every 4–8 hours but does give a dry mouth. Glycopyrronium is also useful by subcutaneous infusion of 0.6–1.2 mg in 24 hours.

Other physical symptoms

People with cancer may develop other physical symptoms caused directly by the tumour (e.g. hemiplegia due to brain secondaries) or indirectly (e.g. bleeding or venous thromboembolism due to disturbances in coagulation). Symptoms may also result from treatment, such as lymphoedema following treatment for breast or vulval cancer, or heart failure secondary to anthracycline or trastuzumab therapy. The principles of holistic assessment, reversal of reversible factors and appropriate involvement of the multiprofessional team should be applied.

Lymphoedema

The pain and disabling swelling associated with lymphoedema can be alleviated through complete decongestive therapy (CDT), a treatment which is a massage-like technique and comprises manual lymphatic drainage, compression bandaging and gentle exercise. Diuretics should not be used. Referral to a specialist lymphoedema therapist or nurse is useful.

Fatigue

Fatigue is a significant and debilitating problem for palliative patients. It has physical, cognitive and affective components; unlike normal tiredness, it is not relieved by usual sleep or rest. An assessment for reversible contributory factors such as anaemia, hypokalaemia or over-sedation due to poorly

Table 10.2 Key non-pharmacological interventions for breathlessness

Intervention	Putative mechanism of action	Most useful
Hand-held fan	Cooling area served by 2nd and 3rd branches of trigeminal nerve Reduces temperature of air flowing over nasal receptors, altering signal to brainstem respiratory complex and so changing respiratory pattern	Reducing length of episodes of SOB on exertion or at rest Gives patient and carer confidence to have an intervention they can use
Exercise	Stops spiral of disability developing Changes muscle structure: less lactic acid produced	Patients who are still quite mobile. In patients who have not developed onset of SOB, reduce/defer symptoms by reducing deconditioning
Anxiety reduction , e.g. CBT (needs skilled clinician to administer) or simple relaxation therapy	Works on central perception of breathlessness reducing impact Interrupting panic/anxiety cycle	People with higher levels of anxiety at baseline (i.e. when first seen) Patients willing to persevere with learning a new skill
Carer support	Reduces carer anxiety and distress which is part of 'total' anxiety-panic cycle	Where carer is isolated, under extra pressures (e.g. looking after elderly parent, going through divorce)
Breathing retraining	Improve mechanical effectiveness respiratory system	Chronic advanced respiratory disease and those with anxiety-related breathlessness
Pacing (finding a balance between activity and rest to achieve aims) and prioritizing (deciding which daily activities are most necessary and focusing energy use on them)	Avoids over-exertion which can lead to exhaustion, inactivity and subsequent deconditioning	Patients who are able and willing to modify daily routines
Neuromuscular electrical stimulation	Increases muscle bulk, simulating effect of exercise	Patients who live alone Those unable to get out to attend rehabilitation group People with a short prognosis People with co-morbidities that prevent exercise

CBT, cognitive behavioural therapy; SOB, short of breath (breathlessness).

optimized medication should be undertaken. Management strategies are:

- **Non-pharmacological:** relaxation, sleep hygiene, resting 'pro-actively' rather than collapsing when exhausted, and planning, pacing and prioritizing daily activities
- **Pharmacological:** low dose methylphenidate or modafinil (central nervous system stimulants), done in conjunction with the specialist palliative care team, may help.

General wellbeing

Corticosteroids are commonly given as a non-specific 'boost' for general wellbeing, but benefits are short-lived and the adverse effects, which include proximal myopathy, are significant. If corticosteroids are to be given, then a short-term course (up to 3 weeks) to cover particular goals, with clear prescribing responsibility, is the best way to ensure net benefit.

Loss of function, disability and rehabilitation

Some of the most pressing concerns include increasing physical frailty, loss of independence, and perceived burden on others. Evidence suggests that functional problems are not routinely assessed, and not as well managed as pain and other symptoms. Rehabilitation can:

- contribute to patients' quality of life by providing strategies for managing declining physical function and fatigue, and by offering resources that might make life

easier for patients and carers (e.g. equipment or a wheelchair)

- support patients' adaptation to disability, helping them to increase social participation and find fulfilment in everyday living
- minimize carer stress and distress.

A referral to physiotherapy or occupational therapy is helpful for patients whose ability to carry out daily activities is compromised by illness or its treatment. However, remember that effective rehabilitation is a team effort and is not solely the domain of nursing and allied health professionals. Doctors also have a major role to play in attending to functional problems and fatigue; they should not see these as inevitable, unavoidable and insoluble.

There is a need to take into account changing performance status as well as changes in goals and priorities. It can be helpful to identify short-term, achievable goals and focus on these. Most patients wish to remain at home for as long as possible, and to die at home, given adequate support. Patients' community rehabilitation needs should not be neglected.

Psychosocial issues

Depression is a common feature of life-limiting and disabling illness and is often missed or dismissed as 'understandable'. However, it may well respond to the usual drugs and/or to non-pharmacological measures such as cognitive behavioural therapy, increased social support (e.g. day therapy) and support for family relationships. Such interventions can make a big difference to the patient's quality of life and the ability to cope with the situation.

Box 10.4 Key points in palliative care

- Patients should always be involved in decisions about their care.
- Quality of life is increased when treatment goals are clearly understood by everyone, including patient and carer.
- The multidisciplinary team can provide a high standard of care but there must be realism and honesty about what can be achieved.
- Hospitalization is sometimes necessary but end-of-life care is often delivered in hospices or the home.
- Care at home should be encouraged for as long as possible, even if the patient's preferred place of death is elsewhere.
- Discussions about end-of-life care planning are best held outside times of crisis, when the patient feels as well as possible, with clinicians with whom they have a good relationship. The results of these discussions must be recorded and made known to everyone involved in the patient's care.

EXTENDING PALLIATIVE CARE TO PEOPLE WITH NON-MALIGNANT DISEASE

The principles of palliative care can be applied throughout medical practice so that all patients, irrespective of care setting (home, hospital or hospice) receive appropriate care from the staff looking after them and have access to SPC services for complex issues. Some principles are outlined in **Box 10.4**. Patients who have chronic non-malignant disease such as organ failures (heart, lung and kidney), degenerative neurological disease and HIV infection:

- have a similar or greater symptom burden than people with cancer
- may live longer with these difficulties
- benefit from a palliative care approach with access to SPC for complex problems.

There may be a less clear end-stage of disease, but the principles of symptom control are the same: holistic assessment, reversal of reversible factors and multiprofessional support.

Patients who have non-malignant disease may have very close relationships with their usual team, and an integrated approach is essential to allow optimization of disease-directed medication as well as palliation. People with non-malignant disease may live for years with a difficult illness and so their palliative care needs to differ in some respects from those of cancer patients (**Table 10.3**). However, symptom management is largely transferable, with some exceptions and extra complexities as outlined below.

Throughout the course of the illness, careful open discussion of possible future options is essential. Early discussion of difficult choices is as helpful for patients who have non-malignant disease as it is for those with cancer and these discussions are ideally held when the patient is relatively well and outside an acute episode. Discussions delayed until the crisis of acute admission may lead to acceptance of an invasive treatment that is later regretted by the patient.

Heart failure

There are special considerations with respect to cardiac medication in advanced disease:

- Drugs that are commonly used in palliative care but usually contraindicated in heart failure, such as

Table 10.3 Differences between palliative care for people with malignant and non-malignant diseases

Cancer	Non-malignant disease
Standard treatment regimens even in advanced disease	Advanced disease often needs bespoke pharmacological interventions, which may interact with palliative drugs. Close teamwork is essential to avoid adversely affecting outcomes, e.g. in use of opioids and many other drugs
Relatively new diagnosis (weeks to months)	Usually many years of illness with loss of social networks, employment and practical support
Sudden death is rare (although it can happen, e.g. pulmonary embolus, neutropenic sepsis)	Sudden death is relatively frequent as a result of cardiovascular/diabetic complications (e.g. in chronic kidney disease)
Cancer and associated problems are the main morbidities	Co-morbidities due to disease or treatment often cause most problems and shape end-of-life care
Prognosis is usually predictable	Prognosis difficult to determine: many 'near death experiences', admissions and recoveries occur
Support from SPC services is often started early in the disease course	Main support may be from a medical unit, e.g. dialysis unit
Standard hospice services (e.g. day therapy) often suit treatment patterns well	Standard hospice service may not be offered (clinician ignorance) or may not be feasible (e.g. for dialysis patient attending hospital 3 days a week)

amitriptyline and NSAIDs, may be appropriate at the very end-of-life.

- Sudden death is more common than in patients who have malignancy and a patient may have an implanted defibrillator in place. If present, these devices should be re-programmed to pacemaker mode in advanced disease because they have not been shown to improve survival in severe heart failure and it will be distressing for patient, carer and staff if they discharge as the patient is dying.
- Peripheral oedema can become a major problem and more resistant to diuretic therapy, therefore careful balancing of medication regimens is required. Ultimately symptom relief is prioritized over renal function.
- Medications should be rationalized to reduce polypharmacy, e.g. ceasing drugs prescribed to reduce long-term secondary risk (e.g. statins) and continuing drugs that help symptom control (including angiotensin converting enzyme inhibitors, which benefit symptoms as well as survival). Beta blockers may have to be stopped if the patient can no longer maintain non-symptomatic hypotension.

Chronic respiratory disease

Chronic obstructive pulmonary disease (COPD)

COPD is the most common chronic respiratory disease. Patients may live increasingly restricted lives for years, rather

than the months or weeks that are common once someone with cancer becomes breathless. Patients usually reach late middle age or old age before becoming very disabled, and an elderly spouse often has to carry significant physical burdens.

Because of the risk of dependency, falls and memory problems, non-pharmacological approaches to anxiety are more appropriate than benzodiazepines (Table 10.2). Short-acting benzodiazepines should be reserved for severe panic episodes.

Palliative care breathlessness services can be very helpful for those unable to comply with pulmonary rehabilitation. Emergency admissions to hospital for non-medical reasons are often due to anxiety and the support offered by community palliative care services working with respiratory teams can help prevent these.

Ventilatory support

For many patients who have respiratory failure, non-invasive ventilation has superseded the use of intermittent positive pressure ventilation (IPPV) on intensive therapy units. However, there are patients who are likely to need IPPV during admission for an acute exacerbation. For some of this group, life has become burdensome rendering the net benefit for this procedure less, or negligible. These patients should be put in contact with hospice services when they are relatively stable (not during acute exacerbations), anticipating an alternative place of admission in the event of subsequent deteriorating health.

Other chronic respiratory diseases

Other chronic respiratory illnesses that often require palliative care include:

- **Diffuse parenchymal lung disorders (interstitial lung disease) (ILD):** this has a trajectory similar to cancer with rapidly developing breathlessness and cough. The breathlessness of ILD is particularly frightening but may respond well to opioids: early access to hospice services is particularly relevant to help with symptom control and anxiety.
- **Cystic fibrosis:** patients are teenagers or young adults who usually have known their respiratory team all their lives. An integrated team involving SPC clinicians ensures good symptom control and provides useful support when difficult decisions have to be made about treatments (e.g. lung transplant), as well as offering psychosocial care to the family.
- **Primary pulmonary hypertension:** patients are often young and treated far from home in specialist centres. They require symptom control in close consultation with the medical team, and it is essential that any dependent children receive the care they need.

Opioid titration in non-malignant respiratory disease

In non-malignant respiratory disease, opioid titration may need to follow a different pattern from that used in malignant disease, in which many patients are already on opioids for pain control before they develop breathlessness. The evidence is not clear but some clinicians recommend a cautious approach for these chronically breathless patients who have non-malignant disease, rather than immediately starting a daily dose of 10 mg of modified release morphine.

Renal disease

All care for patients who have end-stage chronic kidney disease (CKD) is directed toward maintenance or improvement of renal function. Prescribing is complicated, particularly if patients are receiving dialysis. Care must be taken not to inadvertently cause renal damage with potentially nephrotoxic medication, and close liaison with the renal team is mandatory.

In patients who have CKD, co-morbidities such as cardiovascular disease, diabetes or osteoporosis may cause greater problems than the renal disease. Those with a fluctuant course of symptoms, such as the 25–33% who have co-existing cardiac disease, bear disproportionately greater physical and psychological burdens.

Patients who are on dialysis

Patients attend three times per week (and receive social support from this). Thus additional attendance at hospice day therapy service may be too tiring. If further support from SPC services is needed, then outpatient clinics, community support (for patient and/or carer) or even admission may be more suitable.

Withdrawal of dialysis

Withdrawal of dialysis is necessary if the effort of attendance becomes too great when there is little improvement in quality of life and the impact of other co-morbidities becomes intrusive.

If there is no residual renal function, survival after withdrawal of dialysis is likely to be a few days at most. In contrast, patients who have some residual function (usually those who have had dialysis for only a few weeks or months) may live for months or even a year after withdrawal. Patients and carers need to understand these differences in order to make informed choices.

Patients who are not on dialysis

Maximizing and preserving remaining renal function is a critical consideration in deciding which medications can or should be prescribed:

- Medication that accelerates loss of renal function may markedly reduce survival in those patients who are able to live months or years with very little remaining renal function.
- The renal impact of both dose and drug choice must be taken into account, e.g. morphine and diamorphine metabolites accumulate in end-stage renal dysfunction, thus strong opioids such as alfentanil or fentanyl should be used instead.

Close liaison with the medical team is essential for drug prescribing.

Neurological disease

People who suffer from chronic degenerative neurological diseases have considerable burden of palliative care needs including:

- Difficulties in swallowing (e.g. in motor neurone disease)
- Loss of mental capacity – the ability to understand, weigh up, come to a decision and communicate that decision.

Ideally, discussions regarding the patient's wishes should take place in advance, if the patient is able to do this, so that these can be supported.

FURTHER READING

Murtagh F, Addington-Hall J, Higginson I. End-stage renal disease: a new trajectory of functional decline in the last year of life. *J Am Geriatr Soc* 2011; 59:304–308.

Motor neurone disease

Motor neurone disease is usually rapidly progressive, often requiring hospice support. Percutaneous endoscopic gastrostomy (p. 222) feeding may be required. In addition, if ventilatory failure develops, nocturnal non-invasive ventilation may be offered. Patients and their carers need to understand:

- why this treatment has been offered (to prevent hypercarbia and morning headache and confusion)
- when this treatment will be withdrawn (when it is no longer helping to maintain or improve quality of life in the face of advancing disease).

Patients need to be given a clear understanding of what alternative symptom control will be offered at withdrawal.

Multiple sclerosis

Pain is often prominent in multiple sclerosis because of muscle spasm: patients may become too disabled to attend outpatient clinics and then receive very little surveillance. Hospice day therapy service, rehabilitation and support for the family can make a huge impact on quality of life.

Dementia

Dementia-related palliative care needs arise in the context of:

- neurological conditions that tend to occur in older people (Alzheimer's disease and multi-infarct dementia)
- neurological conditions that also affect younger people (e.g. Parkinson's disease, multiple sclerosis, Huntington's disease).

Dementia poses special problems with respect to inpatient palliative care. For example, in the UK, many hospice inpatient units will not accept mobile patients who have dementia because the patient's safety cannot be guaranteed. However, they will care for those at the end-of-life with other SPC needs, for example a distressed young family or pain, and will often support other services by providing advice on symptom control.

Care of the dying

Most people express a wish to die in their own homes, provided their symptoms are controlled and their carers are supported. However, patients die in any setting and so all healthcare professionals should be proficient in end-of-life care.

Reports of inadequate hospital care have led to the development of integrated pathways of care for the dying. Pathways act as prompts of care, including psychological, social, spiritual and carer concerns in those who are diagnosed as dying. The latter is a decision reached by a multiprofessional team through careful assessment of the patient and exclusion of reversible causes of deterioration.

Do not attempt resuscitation (DNAR) orders

- The resuscitation status of every patient should be discussed by senior doctors at the time of admission and the decision documented in the notes.
- Many hospitals have specific DNAR forms. Deciding a person's resuscitation status is a careful balance of risk versus benefit. The patient's co-morbidities and pre-morbid quality of life should be taken into account.
- Involve the patient and family in this discussion, and explain the medical reasoning behind the decision. If the patient requests that CPR is not performed in the event of cardio-pulmonary arrest, those wishes should be respected.

Box 10.5 Stages in the Liverpool Care Pathway – an end-of-life tool

- Recognition of the dying phase
- Initial assessment (which includes the patient's and carers' understanding and psychological state)
- Ongoing assessment and monitoring
- Care of the carers after the patient's death (see Table 10.2)

Remember that a decision not to resuscitate a patient is not the same as the decision to withhold other treatment. A patient who is not for resuscitation may still be eligible for antibiotics, fluids, endoscopy and even surgery. Management should remain positive, allowing the patient to die free of distress and with dignity.

An end-of-life tool: the Liverpool Care Pathway

The Liverpool Care Pathway (LCP) is a four-stage end-of-life tool designed to transfer the standard of hospice care of the dying into the hospital (Box 10.5). Now adapted for any setting, it is the most commonly used pathway for care of the dying in the UK and in several other countries. There have been no trials comparing effectiveness of any end-of-life care pathways against usual care without a pathway, but serial UK national hospital audits have been able to assess and monitor the level of care documented against the standards set in the LCP.

The LCP has provision for departures from the 'prompts of care', e.g. discontinuation of intravenous antibiotics or parenteral fluids, if a clinical need can be demonstrated. The patient is reviewed regularly (at least daily). Occasionally, the patient improves whilst on the pathway and can be returned to usual care if this is deemed more appropriate by the clinical team. For those who do not improve, the LCP prompts advanced prescription of medication to ease the symptoms most likely to arise in the dying phase (pain, breathlessness, nausea, agitation and excess respiratory secretions) to allow timely action.

Engagement with family and carers is vital, and it should not be assumed that they will recognize or understand signs of imminent death. The LCP has supportive information leaflets that carers should find useful.

RHEUMATOLOGICAL AND MUSCULOSKELETAL DISORDERS

Many common locomotor problems are short-lived and self-limiting or settle with a course of simple analgesia and/or physical treatment; e.g. physiotherapy or osteopathy. However, they represent 20–30% of the workload of the primary care physician, where non-inflammatory problems predominate. Recognition and appropriate early treatment of many painful rheumatic conditions may help reduce the incidence of chronic pain disorders. Early recognition and subsequent treatment of inflammatory arthritis by specialist multidisciplinary teams leads to better symptom control and prevents long-term joint damage and disability. The patient should always be included when decisions about treatment are being discussed. Pamphlets and websites offer helpful advice for patients, and their use should be encouraged.

THE NORMAL JOINT

There are three types of joints: fibrous, fibrocartilaginous and synovial.

Fibrous and fibrocartilaginous joints

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis and the costochondral joints. Skull sutures are fibrous joints.

Synovial joints

These (Fig. 11.1) include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal).

They possess a cavity and permit the opposed cartilaginous articular surfaces to move painlessly over each other. Movement is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse.

Synovium and synovial fluid. The joint capsule, which is connected to the periosteum, is lined with synovium, which is a few cells thick and vascular. Its surface is smooth and non-adherent and is permeable to proteins and crystalloids. As there are no macroscopic gaps, it is able to retain normal joint fluid even under pressure. Macrophages and fibroblast-like synoviocytes form the synovial layer by cell-to-cell interactions mediated by cadherin-II. The synoviocytes release hyaluronan into the joint space, which helps to retain fluid in the joint. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium.

Juxta-articular bone

The bone which abuts a joint (epiphyseal bone) differs structurally from the shaft (metaphysis) (see Fig. 11.32). It is highly vascular and comprises a light framework of mineralized

Figure 11.1 Normal synovial joint.

collagen enclosed in a thin coating of tougher, cortical bone. The ability of this structure to withstand pressure is low and it collapses and fractures when the normal intra-articular covering of hyaline cartilage is worn away as in osteoarthritis (OA; see p. 512). Loss of surface cartilage also leads to the abnormalities of bone growth and remodelling typical of OA (see p. 512).

Bone structure and physiology

Bone structure and physiology is discussed on [page 549](#).

Hyaline cartilage

Hyaline cartilage forms the articular surface and is avascular. It relies on diffusion from synovial fluid for its nutrition. It is rich in type II collagen that forms a meshwork enclosing giant macromolecular aggregates of proteoglycan. These heterogeneous macromolecules comprise protein chains with side-chains of the carbohydrates keratan and chondroitin sulphate (aggrecans). These molecules have a negative charge and retain water in the structure by producing a dynamic tension between the retaining force of the collagen matrix and the expansive effect of osmotic pressure. Intermittent pressure from 'loading' of the joint is essential to normal cartilage function and encourages movement of water, minerals and nutrients between cartilage and synovial fluid. Chondrocytes secrete collagen and proteoglycans and are embedded in the cartilage. They migrate towards the joint surface along with the matrix they produce.

Ligaments and tendons

These structures stabilize joints. Ligaments are variably elastic and this contributes to the stiffness or laxity of joints (see p. 559). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an *enthesis* and may be the site of inflammation.

Components of extracellular matrix

All connective tissues contain an extracellular matrix of macromolecules: collagens, elastins, non-collagenous glycoproteins and proteoglycans, in addition to cells, e.g. synoviocytes.

There are several different types of cell surface receptors that bind extracellular matrix proteins including the integrins, CD44 and the proteoglycan family of receptors, e.g. *syndecans*.

Collagens. Collagens consist of three polypeptide (α) chains wound into a triple helix. These alpha chains contain repeating sequences of Gly-x-y triplets, where x and y are often prolyl and hydroxyprolyl residues. Collagen fibres show genetic heterogeneity, with genes on at least 12 chromosomes. Hyaline cartilage is 90% type II (COL2A1). There are several classes of collagen genes, based on their protein structures, and abnormalities of these may lead to specific diseases (see p. 560).

Elastin, secreted as tropoelastin, is an insoluble protein polymer and is the main component of elastic fibres.

Glycoproteins. Fibronectin is the major non-collagenous glycoprotein in the extracellular matrix. Its molecule contains a number of functional domains, or cell recognition sites that bind ligands and are involved in cellular adhesion. Fibronectin plays a major role in tissue remodelling. Its production is stimulated by interferon-gamma (IFN- γ) and by transforming growth factor-beta and inhibited by tumour necrosis factor and interleukin-1.

Proteoglycans. These proteins contain glycosaminoglycan (GAG) side-chains and are of variable form and size. Many different molecules have been identified at different sites in connective tissue. Their function is to bind extracellular matrix together, retain soluble molecules in the matrix and assist with cell binding. Abnormalities of any of these structures may lead to periarticular or articular symptoms and/or predispose to the development of arthritis.

Joint sensation

The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Connective tissue degradation

Connective tissue constantly undergoes repair and remodelling. Degradation is mediated by enzymes such as aggrecanase and matrix metalloproteinases (MMPs) which require zinc and act at a neutral pH. There are several MMPs which act on different collagens, e.g. the gelatinases (MMP-2 and -9), which degrade denatured collagen. MMPs also act on non-collagen proteins, e.g. the stromelysins (MMP-3, -10, -11), which degrade proteoglycans and fibronectin.

The turnover of normal collagen is initiated by cytokines, e.g. interleukin-1 synthesized by chondrocytes. Activation of latent MMPs and tissue plasminogen activator then occurs.

Two inhibitors, TIMP (Tissue Inhibitor of Metalloproteinase) and plasminogen activator inhibitor-1 (PAI-1), inhibit degradation during matrix remodelling.

Skeletal muscle

This consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils which cause muscle contraction in a similar way to myocardial muscle (p. 671). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle) and forms the tendon which attaches to the bone surface (enthesis).

CLINICAL APPROACH TO THE PATIENT

Taking a musculoskeletal history

The following questions are helpful in assessing the problem and making a diagnosis. A history can often lead to a diagnosis as pattern recognition is the key to diagnosis in rheumatic diseases.

- **Has there been recent trauma?**

Pain

- **Where is it? Is it localized or generalized?** The pattern of joint involvement is a useful clue to the diagnosis (e.g. distal interphalangeal joints in nodal osteoarthritis).
- **Is it arising from joints, the spine, muscles or bone, with local tenderness?** Soft tissue lesions and inflamed joints are locally tender.
- **Could it be referred from another site?** Joint pain is localized but may radiate distally – shoulder to upper arm; hip to thigh and knee.
- **Is it constant, intermittent or episodic?** How severe is it – aching or agonizing?
- **Are there aggravating or precipitating factors?** Is it made worse by activity and eased by rest (mechanical) or worse after rest (inflammatory).
- **Are there any associated neurological features?** Numbness, pins and needles and/or loss of power suggest 'nerve' involvement. The distribution of symptoms is a useful clue to the nerve or nerve root affected.

Stiffness

- **Is it generalized or localized?** Spine or joint stiffness is common after injury.
- **Does it affect the limb girdles or periphery?**
- **Is it worse in the morning and relieved by activity?**
 - Morning joint stiffness for more than 15 min each morning – think of inflammatory arthritis.
 - Morning spinal stiffness in younger adults – think of ankylosing spondylitis (p. 527).
 - Morning shoulder and pelvic girdle stiffness and pain in a patient over 55 years may be polymyalgia rheumatica (p. 542).

Swelling

- **Is it of one joint, or of several?** Look for symmetry or asymmetry, and/or a peripheral or proximal pattern. An acute monoarthritis may be due to trauma, gout (in a middle-aged male) or sepsis (fever or immunosuppression).
- **Is it constant or does it come in short-lived or longer episodes?**
- **Is there associated inflammation** (redness and warmth)?

Gender

Gout (see p. 530), reactive arthritis (p. 529) and ankylosing spondylitis (p. 527) are more common in men. Rheumatoid arthritis and other autoimmune rheumatic diseases are more common in women.

Age

- **Is the person young, middle-aged or older?**
- **How old was the patient when the problem first started?** Osteoarthritis (see p. 512) and polymyalgia rheumatica (p. 542) rarely affect the under-50s. Rheumatoid arthritis starts most commonly in women aged 30–50 years.

General health

- **Is there any associated ill-health or other worrying feature,** such as weight loss or fever?
- **Are there other associated medical conditions that may be relevant?** Psoriasis (see p. 1207) or inflammatory bowel disease is associated with spondyloarthritis (see p. 1004). Charcot's joints (p. 547) are seen in diabetics.

Medication

Could a drug be a cause? Diuretics may precipitate gout in men and older women. Hormone replacement therapy or the oral contraceptive pill may precipitate systemic lupus erythematosus (SLE) (p. 535). Steroids can cause avascular necrosis. Some drugs cause a lupus-like syndrome (p. 535).

Race

Is this relevant? Sickle cell disease causes joint pain in young black Africans, but osteoporosis (see p. 552) is uncommon in older black Africans.

Past history

Have there been any similar episodes or is this the first? Are there any clues from previous medical conditions? Gout is recurrent; the episodes settle without treatment in 7–10 days. Acute episodes of palindromic rheumatism may predate the onset of rheumatoid arthritis (see p. 519).

Family history

Does anyone in the family have a similar problem or another related disorder?

Occupational history

What job does the patient do? This can be a factor in soft tissue problems and osteoarthritis (e.g. in heavy labourers and dancers). Work-related problems, particularly in those who use a keyboard, are becoming more common and are complained of more.

Psychosocial history

The biopsychosocial model of disease is highly relevant to many rheumatic disorders:

- **Has there been any recent major stress in family or working life? Could this be relevant?** Stress rarely causes rheumatic disease but may precipitate a flare-up of inflammatory arthritis. It reduces a person's ability to cope with pain or disability.
- **Has there been an injury for which a legal case for compensation is pending?**

Extent of disability

The World Health Organization describes the impact of disease on an individual in terms of:

- **Impairment:** any loss or abnormality of psychological or anatomical structure or function

- **Disability** (activity limitation): any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being
- **Handicap** (participation restriction): a disadvantage for an individual resulting from an impairment or disability that limits or prevents the fulfilment of a role that is normal for that individual.

The patient's own perception of limitation must be taken into account during assessment, as well as the impact of physical causes due to disease. Subjective and objective assessments must be made. Quality of life (QoL) involves physical and psychosocial factors. The aim of treatment is to reduce or cure physical and/or psychological disease and to reduce the impact of any impairment or disability on the individual. A variety of different standard questionnaires is used to assess pain, disease impact and outcome (e.g. Health Assessment Questionnaire, HAQ; Arthritis Impact Measurement Scale, AIMS).

Examination of the joints

Always observe a patient, looking for disabilities, as he or she walks into the room and sits down. General and neurological examinations are often necessary. Guidelines for rapid examinations of the limbs and spine are shown in [Practical Box 11.1](#).

Examining an individual joint involves three stages: looking, feeling and moving ([Table 11.1](#)). A screening examination of the locomotor system, known by the acronym GALS (Global Assessment of the Locomotor System) has been devised. X-ray or ultrasound of the joint often forms an integral part of the examination.

Investigations

Investigations are unnecessary in many of the common musculoskeletal problems; the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

Useful blood screening tests

- **Full blood count**
 - *Haemoglobin*. Normochromic, normocytic anaemia suggests chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, sometimes due to non-steroidal anti-inflammatory drug (NSAID) induced gastrointestinal bleeding.
 - *White cell count*. Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia occurs with viral illnesses or active systemic lupus erythematosus (SLE). Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in the Churg–Strauss syndrome ([p. 847](#)).
 - *Platelets*. Raised platelets occur with any chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression.
- **Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)**. An increase of these reflects inflammation. Plasma viscosity is also raised in inflammatory disease.
- **Bone and liver biochemistry**. A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is seen with

Practical Box 11.1

Rapid examinations of the limb and spine

Rapid examination of the upper limbs

- *Raise arms sideways to the ears (abduction). Reach behind neck and back.* Difficulties with these movements indicate a shoulder or rotator cuff problem.
- *Hold the arms forward, with elbows straight and fingers apart, palm up and palm down.* Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting and deformity.
- *Place the hands in the 'prayer' position with the elbows apart.* Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis or skin disease. Painful restriction of the wrist limits the person's ability to move the elbows out with the hands held together.
- *Make a tight fist.* Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.

Rapid examination of the lower limbs

- *Ask the patient to walk* a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.
- *Ask the patient to stand on each leg.* Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test).
- *Watch the patient stand and sit,* looking for hip and/or knee problems.
- *Ask the patient to straighten and flex each knee.*
- *Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated.* This tests for painful restriction of hip or knee. Abnormal hips or knees must be examined lying.
- *Move each ankle up and down.* Examine the ankle joint and tendons, medial arch and toes whilst standing.

Rapid examination of the spine

Stand behind the patient.

- *Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways, and (d) look over each shoulder, flexing and extending and sideflexing the neck.* Observe abnormal spinal curves – scoliosis (lateral curve), kyphosis (forward bending) or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse whilst standing and bending. Leg length inequality leads to a scoliosis which decreases on sitting or lying (the lengths are measured lying).
- *Ask the patient to lie supine.* Examine any restriction of straight-leg raising (see disc prolapse, below).
- *Ask the patient to lie prone.* Examine for anterior thigh pain during a femoral stretch test (flexing knee whilst prone), which indicates a high lumbar disc problem.
- *Palpate the spine and buttocks* for tender areas.

drug-induced toxicity. For other investigations of bone, see [page 550](#).

Other blood and urine tests

- Protein electrophoretic strip (and/or immunofixation), serum free light chain testing and urinary Bence Jones protein – to exclude myeloma as a cause of a raised ESR.
- Serum uric acid – for gout.
- Antistreptolysin-O titre – in rheumatic fever.

Serum autoantibody studies

- **Rheumatoid factors (RFs)** (see also [p. 518](#)). Rheumatoid factors are detected by enzyme linked immunoabsorbent assay (ELISA). RFs are antibodies

Table 11.1 Examination of the joint

LOOK at the appearance of the joint	Swelling – could be bony, fluid or synovial Deformity – <i>valgus</i> , where the distal bone is deviated laterally (e.g. knock-knees or genu valgum) <i>Varus</i> where the distal bone is deviated medially (bow-legs or genu varum) <i>Fixed flexion or hyperextension</i> Rash – especially psoriasis Muscle wasting – easier to see in large muscles like the quadriceps Scars – from surgery or trauma Signs of inflammation Symmetry – are the right and left joints (e.g. hips, knees, any other paired joint) the same? If not which do you think is abnormal?
FEEL	Swelling – <i>fluid swelling</i> (effusion) usually represents increased synovial fluid in inflammatory arthritis, but can be due to blood or pus <i>Synovial swelling</i> is rubbery or boggy and usually occurs in inflammatory arthritis <i>Bony swelling</i> , such as Heberden's nodes in the fingers is usually seen in osteoarthritis Warmth – a warm joint may be inflamed or infected Tenderness – may represent joint inflammation, but many people have chronic tenderness all over the body (e.g. in fibromyalgia)
MOVE	Active movement – is the range full and pain-free? Is the movement fluid? In the hands – can the patient perform fine movements? In the legs – can the patient walk properly? Compare movements on the right and left side – are they symmetrical? Is there crepitus when the joint is moved? If active movement is limited try passive movement. In a joint problem both will usually be affected. If it is a muscle or nerve problem passive movement may remain full.

(usually IgM, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of people with rheumatoid arthritis (RA), but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Table 11.2).

■ **Anti-citrullinated peptide antibodies (ACPA).**

These antibodies are directed against citrullinated antigens, vimentin, fibrinogen, alpha enolase and type II collagen. They are measured by an ELISA technique and are present in up to 80% of people with RA. They have a high specificity for RA (90% with a sensitivity of 60%). They are helpful in early disease when the RF is negative to distinguish it from acute transient synovitis (see Box 11.6, p. 519). Positivity for RF and/or ACPA is associated with a worse prognosis and an increase in the likelihood of bony erosions in people with RA.

Table 11.2 Conditions in which rheumatoid factor is found in the serum

Autoimmune rheumatic diseases	RF (IgM) %
Rheumatoid arthritis	70
Systemic lupus erythematosus	25
Sjögren's syndrome	90
Systemic sclerosis	30
Polymyositis/dermatomyositis	50
Juvenile idiopathic arthritis	Variable
Viral infections	Hyperglobulinaemias
Hepatitis	Chronic liver disease
Infectious mononucleosis	Sarcoidosis
Cryoglobulinaemia	Normal population
Chronic infections	Elderly
Tuberculosis	Relatives of people with RA
Leprosy	
Infective endocarditis	
Syphilis	

Table 11.3 Conditions in which serum antinuclear antibodies are found

	(%)
Systemic lupus erythematosus	95
Systemic sclerosis	70
Sjögren's syndrome	80
Polymyositis and dermatomyositis	40
Rheumatoid arthritis	30
Juvenile idiopathic arthritis	Variable
Other diseases	
Autoimmune hepatitis	100
Drug-induced lupus	>95
Myasthenia gravis	50
Idiopathic pulmonary fibrosis	30
Diabetes mellitus	25
Infectious mononucleosis	5–10
Normal population	8

- **Antinuclear antibodies (ANAs).** These are detected by indirect immunofluorescent staining of fresh-frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures (see Box 11.16, p. 537). ANA is used as a screening test for systemic lupus erythematosus (SLE) and systemic sclerosis (SSc) – a negative ANA makes either condition highly unlikely – but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Table 11.3).
- **Anti-double-stranded DNA (dsDNA) antibodies.** These are usually detected by a precipitation test (Farr assay), by ELISA, or by an immunofluorescent test using *Crithidia luciliae* (which contains double-stranded DNA). Raised anti-dsDNA is highly specific for SLE and the levels usually rise and fall in parallel with disease activity so can be used to monitor the level of treatment required.
- **Anti-extractable nuclear antigen (ENA) antibodies** (see Box 11.16, p. 537). These produce a speckled ANA fluorescent pattern, and can be identified by ELISA. The most commonly measured ENAs are:

- *Anti-Ro and anti-La*, which occur in Sjögren's syndrome and SLE
- *Anti-Sm*, which is highly specific for SLE
- *Anti-Jo-1*, which is the commonest of the anti-tRNA synthetase enzymes that occur in some people with dermatomyositis or polymyositis
- *Anti-topoisomerase I (anti-Scl 70)*, which is specific for SSc
- *Anti RNA-polymerase I and III*, which occur in SSc and are associated with pulmonary fibrosis.
- **Anti-neutrophil cytoplasmic antibodies (ANCA)** (see p. 544). These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosomes. They are strongly associated with small-vessel vasculitis. Two major clinically relevant ANCA patterns are recognized on immunofluorescence:
 - *Proteinase 3 (PR3-ANCA)*, also called cytoplasmic or cANCA, producing a granular immunofluorescence and seen in Wegener's granulomatosis,
 - *Myeloperoxidase (MPO-ANCA)*, also called perinuclear or pANCA, producing a perinuclear stain and seen in microscopic polyarteritis (polyangiitis) and Churg–Strauss syndrome.
- **Antiphospholipid antibodies** (see p. 538). These are detected in the antiphospholipid syndrome (see p. 538).
- **Immune complexes**. Immune complexes are infrequently measured, largely because of variability between assays and difficulty in interpreting their meaning. Assays based on the polyethylene glycol precipitation method (PEG) or C1q binding are available commercially.
- **Complement**. Low complement levels indicate consumption and suggest an active disease process in SLE.

Joint aspiration

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The appearance of the fluid is an indicator of the level of inflammation. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis (see [Practical Box 11.2](#), p. 508).

Examination of synovial fluid

Aspiration and analysis of synovial fluid are always indicated when an infected or crystal induced arthritis is suspected, particularly a monoarthritis. Normal fluid is clear and straw coloured and contains <3000 WBC/mm³. Inflammatory fluid is cloudy and contains >3000 WBC/mm³. Septic fluid is opaque and less viscous and contains up to 75 000 WCC/mm³. There is much overlap.

Polarized light microscopy is performed for crystals.

- **Gout**: negatively birefringent, needle-shaped crystals of sodium urate
- **Pyrophosphate arthropathy (pseudogout)**: rhomboidal, weakly positively birefringent crystals of calcium pyrophosphate.

Gram staining is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

Diagnostic imaging and visualization

- **X-rays** can be diagnostic in certain conditions (e.g. established rheumatoid arthritis) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in rheumatoid arthritis, calcification in soft tissue, new bone formation, e.g. osteophytes and decreased bone density (osteopenia) or increased bone density (osteosclerosis):
 1. In acute low back pain (see p. 503), X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, or worse at night or associated with symptoms such as fever or weight loss.
 2. Radiological changes are common in older people and may not indicate symptomatic osteoarthritis or spondylosis.
 3. X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.
- **Ultrasound (US)** is particularly useful for periarticular structures, soft tissue swellings and tendons and for detecting active synovitis in inflammatory arthritis. It is increasingly used to examine the shoulder and other structures during movement, e.g. shoulder impingement syndrome (see p. 500). Doppler US measures blood flow and hence inflammation. US is used to guide local injections.
- **Magnetic resonance imaging (MRI)** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. T₁-weighted is used for anatomical detail, T₂-weighted for fluid detection and short tau inversion recovery (STIR) for the presence of bone marrow oedema. It is more sensitive than X-rays in the early detection of articular and periarticular disease. It is the investigation of choice for most spinal disorders but is inappropriate in uncomplicated mechanical low back pain. Gadolinium injection enhances inflamed tissue. MRI can also detect muscle changes, e.g. myositis.
- **Computerized axial tomography (CT)** is useful for detecting changes in calcified structures but dose of irradiation is high.
- **Bone scintigraphy** utilizes radionuclides, usually ^{99m}Tc, and detects abnormal bone turnover and blood circulation and, although nonspecific, helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging techniques.
- **DXA scanning** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.
- **Positron emission tomography (PET) scanning** uses radionuclides, which decay by emission of positrons. ¹⁸F-Fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. It is used to locate tumours and demonstrate large vessel vasculitis, e.g. Takayasu's arteritis (see p. 789). PET scans are combined with CT to improve anatomical details.
- **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.

COMMON REGIONAL MUSCULOSKELETAL PROBLEMS

(Fig. 11.2)

Pain in the neck and shoulder (Table 11.4)

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. It can follow injury, falling asleep in an awkward position, or prolonged keyboard working. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis seen on X-ray increases after the age of 40 years, but it is not always causal. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm is palpable and tender and may lead to abnormal neck posture (e.g. acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput and is commonly associated with tension headaches. These features are also seen in chronic widespread pain (see p. 509).

Treatment

Patients are given short courses of analgesic therapy along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 510).

Table 11.4 Pain in the neck and shoulder

Trauma (e.g. a fall)
Mechanical or muscular neck pain
Whiplash injury
Disc prolapse – nerve root entrapment (p. 499)
Ankylosing spondylitis
Shoulder lesions:
Rotator cuff tendonitis
Calcific tendonitis or bursitis
Impingement syndrome or rotator cuff tear
Adhesive capsulitis (true 'frozen' shoulder)
Inflammatory arthritis or osteoarthritis
Polymyalgia rheumatica
Fibromyalgia (chronic widespread pain)
Chronic (work-related) upper limb pain syndrome
Tumour

Table 11.5 Cervical nerve root entrapment: symptoms and signs

Nerve root	Sensory changes	Reflex loss	Weakness
C5	Lateral arm	Biceps	Shoulder abduction Elbow flexion
C6	Lateral forearm Thumb and index finger	Biceps Supinator	Elbow flexion Wrist extension
C7	Middle finger	Triceps	Elbow extension
C8	Medial forearm Little and ring fingers	None	Finger flexion
T1	Medial upper arm	None	Finger ab- and adduction

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (Table 11.5).

Cervical spondylosis occurs in the older patient with posterolateral osteophytes compressing the nerve root and causing root pain (see Fig. 22.58, p. 1148), commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan clearly distinguishes facet joint OA, root canal narrowing and disc prolapse.

Treatment

A support collar, rest, analgesia and sedation are used initially as necessary. Patients should be advised not to carry heavy items. It usually recovers in 6–12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (Fig. 11.3). A cervical root block administered under direct vision by an experienced pain specialist may relieve pain while the disc recovers. Neurosurgical referral is essential if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral.

Figure 11.2 Common regional musculoskeletal problems.

Figure 11.3 MRI of cervical spine, showing a large central disc prolapse impinging on the spinal cord (arrow) at the C6/7 level.

Bilateral root pain with or without long track symptoms or signs is a neurosurgical emergency because a central disc prolapse may compress the cervical spinal cord. Posterior osteophytes may cause spinal claudication and cervical myelopathy.

Whiplash injury

Whiplash injury results from acceleration–deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. A simple decision plan based on clinical criteria helps to distinguish those most at risk and who warrant radiography. There is a low probability of serious bony injury if there is:

- no midline cervical tenderness
- no focal neurological deficit
- normal alertness
- no intoxication
- no other painful distracting injury.

CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries commonly lead to litigation.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. Delayed recovery depends in part upon the severity of the initial injury. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder and arm. Subjective symptoms such as headache, dizziness, and poor concentration sometimes accompany this. The subjective nature of these symptoms has led to controversy about their cause. The problem is more commonly seen in industrialized countries where the conflictive nature of the compensation process may actually delay recovery. Non-conflictive means of compensation may lead to a better prognosis.

Treatment is with reassurance (the patient is often distressed and anxious), analgesia, a short-term support collar

Figure 11.4 The shoulder region, showing site of injection and subacromial space.

Box 11.1 Differential diagnosis of 'shoulder' pain

- Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
- Painful shoulders produce secondary muscular neck pain.
- Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
- Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

and physiotherapy. Pain may take a few weeks or months to settle and the patient should be warned of this.

Pain in the shoulder

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff (Fig. 11.4) which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but this may not matter for pain management.

Pain in the shoulder can sometimes be due to problems in the neck. The differential diagnosis of this is shown in Box 11.1. Adhesive capsulitis (true frozen shoulder) is uncommon (see below). Early inflammatory arthritis and polymyalgia rheumatica in the elderly may present with shoulder pain. Shoulder pain is more common in diabetic patients than in the general population.

Rotator cuff (supraspinatus) tendonitis

This is a common cause of shoulder pain at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully; a so-called 'painful arc

syndrome'. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (cf. adhesive capsulitis, see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow. Acromioclavicular osteophytes increase the risk of impingement and may need to be removed surgically.

X-rays or ultrasound are necessary only when rotator cuff tendonitis is persistent or the diagnosis is uncertain.

Treatment

Analgesics, NSAIDs and/or physiotherapy may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (Fig. 11.4). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. Further ultrasound-guided corticosteroid injections may be needed but the long-term benefit is unclear.

Torn rotator cuff

This is caused by trauma but also occurs spontaneously in the elderly and in rheumatoid arthritis (RA). It prevents active abduction of the arm, but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Some patients require arthroscopic surgery.

Calcific tendonitis and bursitis

Calcium pyrophosphate deposits in the tendon are visible on X-ray, but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration or breaking up of the deposit under ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray shows a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis. Aspiration and injection with corticosteroid can help.

Adhesive capsulitis (true 'frozen' shoulder)

This is uncommon but can develop with rotator cuff lesions, or following hemiplegia, chest or breast surgery or myocardial infarction. It causes severe shoulder pain and complete loss of all shoulder movements, including rotation. High doses of NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful. Once the pain settles, arthroscopic release speeds functional recovery.

Pain in the elbow

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or occasionally osteoarthritis.

Epicondylitis

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the insertions of the wrist extensor tendon into the lateral epicondyle ('tennis elbow') and the wrist flexor tendon into the medial epicondyle ('golfer's elbow'). Both are usually unrelated to either sporting activity.

There is local tenderness. Pain radiates into the forearm on using the affected muscles – typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer's elbow. Pain at rest also occurs.

Treatment

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe but needs physiotherapy follow-up to prevent recurrences (Fig. 11.5). Avoid the ulnar nerve when injecting golfer's elbow. Both conditions settle spontaneously eventually, but occasionally persist and require surgical release.

Pain in the hand and wrist (Table 11.6)

Hand pain is commonly caused by injury or repetitive work-related activities. When associated with pins and needles or numbness it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

Figure 11.5 Injection for tennis elbow.

Table 11.6 Pain in the hand and wrist: causes

All ages	Older patients
Trauma/fractures	Nodal OA:
Tenosynovitis:	DIPs (Heberden's nodes)
Flexor with/without triggering	PIPs (Bouchard's nodes)
Dorsal	First carpometacarpal joint
De Quervain's	Trauma – scaphoid fracture
Carpal tunnel syndrome	Pseudogout
Ganglion	Gout:
Inflammatory arthritis	Acute
Raynaud's syndrome (p. 510)	Tophaceous
Chronic regional pain syndrome type I (in this chapter)	
DIPs, PIPs, distal and proximal interphalangeal joints.

Coombes BK, Bisset L, Vicenzino B. Efficacy and safety of corticosteroid injections and other injections for management of tendinopathy: a systematic review of randomised controlled trials. *Lancet* 2010; 376: 1751–1767.

Tenosynovitis

The finger flexor tendons run through synovial sheaths and under loops which hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis. The thickened sheaths are often palpable.

Flexor tenosynovitis causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping and has to be pulled straight. A tender tendon nodule is palpable, usually in the distal palm. Trigger finger or thumb is commoner in diabetic patients.

Dorsal tenosynovitis is less common except in rheumatoid arthritis. The hourglass swelling extends from the back of the hand and under the extensor retinaculum.

De Quervain's tenosynovitis causes pain and swelling around the radial styloid where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

Treatment

Resting, splinting and NSAIDs may help. Local corticosteroids injected alongside the tendon under low pressure (not into the tendon itself) are helpful. Occasionally surgery is needed if symptoms persist.

Carpal tunnel syndrome

This is due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths or bone enlargement can cause it, but it is usually idiopathic. (Causes are discussed on p. 1144.) The history is usually typical and diagnostic with the patient waking with numbness, tingling and pain in a median nerve distribution. The pain radiates to the forearm. The fingers feel swollen but usually are not. Wasting of the abductor pollicis brevis develops with sensory loss in the radial three and a half fingers. The pain may be produced by tapping the nerve in the carpal tunnel (Tinel's sign) or by holding the wrist in flexion (Phalen's test).

Treatment is with a splint to hold the wrist in dorsiflexion overnight. This relieves the symptoms and is diagnostic; used nightly for several weeks it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (avoid the nerve!) helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage produce prolonged latency across the carpal tunnel on nerve conduction studies and require surgical decompression.

Other conditions causing pain

Inflammatory arthritis. This may present with pain, swelling and stiffness of the hands. In RA the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis a finger may be swollen (dactylitis) or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

Nodal osteoarthritis. This affects the DIP and less commonly PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain (p. 514).

First carpometacarpal osteoarthritis. This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in persons with nodal osteoarthritis.

Scaphoid fractures. These cause pain in the anatomical snuffbox. They are not seen immediately on X-ray. A cast is necessary. Untreated scaphoid fractures can eventually cause pain because of failed union.

Ganglion. A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule or tendon sheath. The wrist is a common site. Treatment is not essential as many resolve or cause little trouble, otherwise surgical excision is the best option.

Dupuytren's contracture

This is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis due to abnormal signalling in the Wnt pathway. It causes puckering of the skin and gradual flexion, usually of the ring and little fingers. It is more common in males, Caucasians, in diabetes mellitus and in those who overuse alcohol. A similar fibrosis occurs in the feet and is often more aggressive. It is also associated with Peyronie's disease of the penis – a painful inflammatory disorder of the corpora cavernosa, leading eventually to painless fibrosis and angulation of the penis during erection. Intralesional steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Collagenase injection into the collagen contracted cord improved the amount of movement in one randomized study. Plastic surgical release of the contracture is restricted to those with severe deformity of the fingers.

Pain in the lower back

Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus and other mechanical devices and improved office seating help to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in Table 11.7, and the management of back pain is summarized in Box 11.2.

Investigations

- **Spinal X-rays** are required only if the pain is associated with certain 'red flag' symptoms or signs, which indicate a high risk of more serious underlying problems:
 - a. starts before the age of 20 or after 50 years
 - b. is persistent and a serious cause is suspected
 - c. is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause
 - d. is associated with a systemic illness, fever or weight loss
 - e. is associated with neurological symptoms or signs.
- **MRI** is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better. Interpretation of the relevance of the findings may require a specialist opinion.
- **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be due to malignancy, infection or a metabolic cause. Normal

Table 11.7 Pain in the back (lumbar region): causes

**Box 11.2 Management of back pain**

- Most back pain presenting to a primary care physician needs no investigation.
- Pain between the ages of 20 and 55 years is likely to be mechanical and is managed with analgesia, brief rest if necessary and physiotherapy.
- Patients should stay active within the limits of their pain.
- Early treatment of the acute episode, advice and exercise programmes reduce long-term problems and prevent chronic pain syndromes.
- Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings.
- Psychological and social factors may influence the time of presentation.
- Appropriate early management reduces long-term disability.

ESR and CRP distinguish mechanical back pain from polymyalgia rheumatica, a likely differential in the elderly.

Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. It is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Examination and management

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable and causes local pain and tenderness. It lessens when sitting or lying. Pain relief and physiotherapy are helpful. Acupuncture helps some. Excessive rest should be avoided. Re-education in lifting and exercises help to prevent recurrent attacks of pain. Once a patient develops low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include:

- female sex
- increasing age
- pre-existing chronic widespread pain (fibromyalgia)
- psychosocial factors such as high levels of psychological distress, poor self-rated health and dissatisfaction with employment.

Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult, but some typical syndromes are recognized (see below). They are often associated with but not necessarily caused by radiological spondylosis (see p.1148).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs.

Lumbar spondylosis. The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous joint whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs occasionally start in teenage years or early 20s and often increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority this is initially asymptomatic but visible on MRI as decreased hydration. Later the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (Fig. 11.6). The most common sites of lumbar spondylosis are L5/S1 and L4/L5.

Figure 11.6 MRI of lumbar spine, showing a central disc prolapse at the L4/L5 level (arrow). The signal from the L4/L5 and L5/S1 discs indicates dehydration, while the L3/L4 signal appearance is normal.

Spinal metastasis in L2. The patient had severe back pain and weight loss and prior carcinoma of the breast.

FURTHER READING

Balagué F, Mannion A, Pellise F, Cedraschi C. Non-specific low back pain. *Lancet* 2012; 379: 482–491.

In young people, disc prolapse through an adjacent vertebral endplate produces a Schmorl's node on X-ray. This is painless but may accelerate disc degeneration.

Spondylosis may be symptomless, but it can cause:

- Episodic mechanical spinal pain
- Progressive spinal stiffening
- Facet joint pain
- Acute disc prolapse, with or without nerve root irritation
- Spinal stenosis
- Spondylolisthesis.

Facet joint syndrome. Lumbar spondylosis also causes secondary osteoarthritis of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral and radiates to the buttock. The facet joints are well seen on MRI and may show osteoarthritis, an effusion or a ganglion cyst. Direct corticosteroid injections into the joints under imaging may help but their long-term value is unclear. Physiotherapy to reduce hyperlordosis and reducing weight are helpful.

Fibrositic nodulosis. This causes unilateral or bilateral low back and buttock pain. There are tender nodules in the upper buttock and along the iliac crest. Such nodules are relevant only if they are tender. They are probably traumatic. Local, intralesional corticosteroid injections help.

Postural back pain and sway back of pregnancy. Low back pain is common in pregnancy and reflects altered spinal posture and increased ligamentous laxity. There is usually a hyperlordosis on examining the patient standing. Weight control and pre- and postnatal exercises are helpful, and the pain usually settles after delivery. Analgesics and NSAIDs are best avoided during pregnancy and breast-feeding. Epidurals during delivery are not associated with an increased incidence of subsequent back pain. Poor posture causes a similar syndrome in the non-pregnant, owing to obesity or muscular weakness. Poor sitting posture at work is a frequent cause of chronic low back pain.

Treatment of mechanical back pain

Adequate analgesia to allow normal mobility and avoid bed rest is best, combined with physical treatments such as physiotherapy, back muscle training regimens and manipulation. Manipulation produces more rapid pain relief in some patients. Acupuncture may help. Most episodes recover irrespective of the treatment given. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (Fig. 11.6). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

The episode often starts dramatically during lifting, twisting or bending and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse, usually unilateral and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms is determined by the root affected (Table 11.8). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone). Below L2/L3 it produces lower motor neurone lesions.

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, whilst lying, is positive in a lower lumbar disc prolapse – raising the straight leg beyond 30° produces pain in the leg. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss and urinary retention, which indicate a cauda equina lesion – a neurosurgical emergency (see p. 1135). An upper lumbar disc prolapse produces a positive femoral stretch test; pain in the anterior thigh when the knee is flexed in the prone position.

Treatment

Advise a short period (2–3 days) of bed rest, lying flat for a lower disc but semi-reclining for a high lumbar disc, and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer to a physiotherapist for exercises and preventative advice. An imaging-guided epidural or nerve root canal injection reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemilaminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected it becomes a neurosurgical emergency.

Lamb SE et al. Group cognitive behavioural therapy for low back pain in primary care. *Lancet* 2010; 375:916–923.

Table 11.8 Lumbar nerve root entrapment: symptoms and signs

Nerve root	Sensory changes	Reflex loss	Weakness	Usual disc prolapse
L2	Front of thigh	None	Hip flexion/adduction	L2/3
L3	Inner thigh and knee	Knee	Knee extension	
L4	Inner calf	Knee	Knee extension	L3/4
L5	Outer calf Upper, inner foot	None	Inversion of foot Dorsiflexion of toes	L4/5
S1	Posterior calf Lateral border of foot	Ankle	Plantar flexion of foot	L5/S1

Spinal and root canal stenosis

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and buckling of the ligamentum flavum all contribute to root canal stenosis. This causes nerve root pain or spinal root claudication – pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slower recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

Spinal canal stenosis at more than one level is often associated with severe spondylosis and/or a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, 'heaviness', paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

Spondylolisthesis

This occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit a vertebra to slip, with or without preceding injury. Rarely, a cauda equina syndrome with loss of bladder and anal sphincter control and saddle-distribution anaesthesia develops. It is diagnosed radiologically. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs careful monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis and osteoarthritis of the facet joints.

Diffuse idiopathic skeletal hyperostosis (DISH)

DISH (Forestier's disease) affects the spine and extraspinal locations. It causes bony overgrowths and ligamentous ossification and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic X-ray changes. Ossification at muscle insertions around the pelvis produces radiological 'whiskering'. Similar changes occur at the patella and in the feet. It is commoner in people with metabolic syndrome (high BMI, diabetes mellitus, hypertension and dyslipidaemia; see p. 1006).

Treatment is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

Osteoporotic crush fracture of the spine

Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures develop without trauma, after minimal trauma, or as part of a major accident. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis ('widow's stoop'). They cause disability and reduced QoL. The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral endplates and pedicles. Bone oedema on MRI indicates that a fracture is recent. An underlying tumour and pathological fracture need to be excluded.

Treatment

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and intravenous bisphosphonates or subcutaneous or nasal calcitonin are given to relieve pain. There may be some residual pain and deformity.

The role of percutaneous vertebroplasty and balloon kyphoplasty remains unclear: there are no randomized controlled trials showing any benefit. Both involve inserting a needle through a pedicle into the affected vertebral body under CT guidance with the aim of stabilizing the fracture. Kyphoplasty involves inflating a balloon filled with methyl methacrylate cement in order to restore vertebral shape. Vertebroplasty is the injection of cement alone, without restoring vertebral shape. Pain relief is usual with both but the risks are higher with vertebroplasty. Deciding when to intervene is complicated by the spontaneous recovery that many experience.

Bone density measurement and preventative treatment of osteoporosis are essential (see p. 555).

Septic discitis

Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It is seen on MRI and requires urgent neurosurgical referral.

Ankylosing spondylitis (see p. 527)

Buttock pain and low back stiffness in a young adult suggests ankylosing spondylitis, especially if it is worse at night and in the morning.

Pain in the hip (Table 11.9)

'Hip' refers to a wide area between the upper buttock, trochanter and groin. It is useful to ask the patient to point to the site of pain and its field of radiation. Pain arising from the hip joint itself is felt in the groin, lower buttock and anterior thigh, and may radiate to the knee. Occasionally and inexplicably, hip arthritis causes pain only in the knee.

Osteoarthritis (OA)

OA (see p. 512) is the most common cause of hip joint pain in a person over the age of 50 years. It causes pain in the

Table 11.9 Pain in the hip: causes

Hip region problems	Main sites of pain
Osteoarthritis of hip	Groin, buttock, front of thigh to knee
Trochanteric bursitis (or gluteus medius tendonopathy)	Lateral thigh to knee
Meralgia paraesthetica	Anterolateral thigh to knee
Referred from back	Buttock
Facet joint pain	Buttock and posterior thigh
Fracture of neck of femur	Groin and buttock
Inflammatory arthritis	Groin, buttock, front of thigh to knee
Sacroiliitis (AS)	Buttock(s)
Avascular necrosis	Groin and buttocks
Polymyalgia rheumatica	Lumbar spine, buttocks and thighs
AS, ankylosing spondylitis.

buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp. Sudden onset pain may be associated with an effusion on MRI and can be treated by an ultrasound guided steroid injection.

Lateral hip pain syndrome: trochanteric bursitis and gluteus medius tendonopathy

This may be due to *trochanteric bursitis* and caused by trauma or unaccustomed exercise. It also occurs in inflammatory arthritis. The pain over the trochanter is worse going up stairs, and the trochanter is tender to lie on. Its best management is unclear but exercises help, as may a local corticosteroid injection, although the evidence base for treatment is poor. Surgery is occasionally necessary. Lateral hip pain may be referred from the upper lumbar spine. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome but does not respond to injection. MRI scans have demonstrated this new syndrome.

Meralgia paraesthetica

This causes numbness and burning dysaesthesia (increased sensitivity to light touch) over the anterolateral thigh and may be precipitated by a sudden increase in weight, an injury or during pelvic surgery. It is usually self-limiting but can be helped by amitriptyline or gabapentin at night.

Fracture of the femoral neck

This usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally, a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see p. 553).

Avascular necrosis (osteonecrosis) of the femoral head

This is uncommon but occurs at any age. (Risk factors are discussed on p. 556.) There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion and shows bone marrow oedema.

Inflammatory arthritis of the hip

This produces pain in the groin and stiffness, which are worse in the morning. Rheumatoid arthritis (RA) rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthropathies cause inflammatory hip arthritis in younger people.

Polymyalgia rheumatica

Bilateral hip, buttock and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to polymyalgia rheumatica (see p. 542). Neck and shoulder pain and stiffness are usually also present.

Pain in the knee (Table 11.10)

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections or surgery.

The knee is also a common site of inflammatory arthritis and osteoarthritis. Minor radiographic changes of osteoarthritis (see Fig. 11.11) are common in the over-50s and often coincidental, the cause of the pain being periarticular. Symptomatic osteoarthritis of the knee correlates poorly with the severity of the radiological changes.

Common periarticular knee lesions

Medial knee pain

There may be medial or lateral ligament strain, but the medial ligament is more commonly affected. There is pain at the ligament's insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers.

Treatment is with physiotherapy and a local corticosteroid injection.

Anterior knee pain

Anterior knee pain is common in adolescence. In many cases, no specific cause is found, despite investigation. This is called 'anterior knee pain syndrome' and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patient and parents often need firm reassurance. Abnormal patellar tracking may be a cause and need surgical treatment. Hypermobility of joints causes joint pain, maltracking and rarely recurrent patellar dislocation (see also p. 546).

Pre- and infrapatellar bursitis are caused by unaccustomed kneeling ('housemaid's knee'). There is local pain, tenderness and fluctuant swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

Osgood–Schlatter disease (p. 546) causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs in enthusiastic teenage sports players.

Enthesitis may occur at the patellar end of the tendon (jumper's knee).

Common intra-articular traumatic lesions of the knee

Chondromalacia patellae

This is diagnosed arthroscopically. The retropatellar cartilage is fibrillated. In most cases the pain settles eventually. When there is patellar misalignment it may need surgery, as does recurrent patellar dislocation in adolescent girls.

Torn meniscus

The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young they are resilient but this decreases with age. They can be torn by an injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and swelling within a few hours. The affected side is tender. If the tear is large the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 11.7). In most circumstances, especially in active sportsmen, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary osteoarthritis. The long-term benefit of early repair of tears is not yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

Torn cruciate ligaments

Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often co-exist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90°, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is

the investigation of choice. Such injuries need urgent orthopaedic referral, reconstructive surgery usually being necessary in young active adults. There is a significant incidence of secondary OA.

Osteochondritis dissecans

This occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or 'giving way' occurs. The lesion is seen on a tunnel-view X-ray, but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

Spontaneous osteonecrosis of the knee (SONK)

This may occur spontaneously or after injury. There is local pain and there are marked bone marrow changes on MRI or SPECT-CT. Weight-bearing must be avoided. Pamidronate by infusion is sometimes used. It may progress to bone infarction and require replacement surgery.

Occasionally, spontaneously or after trauma, osteonecrosis of the knee is associated with severe pain and striking findings on MRI, which is often called SONK (spontaneous osteonecrosis of the knee).

Knee joint effusions

An effusion of the knee causes swelling, stiffness and pain. The pain is more severe with an acute onset and with increasing inflammation, because of stretching of the capsule that contains the pain receptors. A full clinical history must include a past medical, family and drug history.

Inflammatory arthritis affects the knees and causes warmth and swelling. An acute inflammatory monoarthritis of the knee is a common presentation of a spondyloarthritis and occasionally is the first sign of RA.

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, or gout in the middle-aged male, or to gout or pseudogout in an older male or female. A cool, clear, viscous effusion is seen in elderly people with moderate or severe symptomatic OA (see p. 512).

Examination

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly (the 'patellar tap' sign) with the knee held straight and relaxed. Small effusions also demonstrate the 'bulge' sign when the patient is lying with the quadriceps relaxed. For this, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

Investigations

These are (a) blood tests, and (b) aspiration (Fig. 11.8) and examination of the knee effusion. The basic technique of aspiration is described in [Practical Box 11.2](#).

Figure 11.7 MRI of a knee, showing a complete tear of the posterior horn of the medial meniscus, extending to its lower surface (arrow).

Practical Box 11.2

Joint aspiration

This is a sterile procedure which should be carried out in a clean environment

Explain the procedure to the patient; obtain consent.

1. Decide on the site to insert the needle and mark it.
2. Clean the skin and your hands scrupulously; remove rings and wristwatch. Put on gloves.
3. Draw up local anaesthetic (and corticosteroid if it is being used) and then use a new needle.
4. Warn the patient, insert the needle, injecting local anaesthetic as it advances and, if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid clear or slightly cloudy) or send for microbiological tests.
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens, or if they become febrile, since this might indicate an infected joint.

Spontaneous osteonecrosis of the knee. SPECT-CT showing a high signal in the posterior medial femoral condyle.

Haemarthrosis of the knee

This is caused by:

- Trauma: meniscal, cruciate or synovial lining tear
- Clotting or bleeding disorders: such as haemophilia, sickle cell disease or von Willebrand's disease.

Popliteal cyst (Baker's cyst). In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The semimembranosus bursa in some individuals has a valve-like connection to the knee. This allows the effusion to flow into the bursa but not back. The cyst is best seen and felt in the popliteal fossa with the patient standing.

Ruptured popliteal cyst. A popliteal cyst may rupture if the patient is mobile. Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf. Dependent oedema of the ankle develops and the knee effusion reduces dramatically in size and may be undetectable.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). However, the diagnosis is often missed and treated inappropriately with

Table 11.11 Pain in the foot and heel: causes

anticoagulants. A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 789). Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

Pain in the foot and heel (Table 11.11)

The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

There are two common types of foot deformity:

- **Flat feet:** stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible.
- **High-arched feet:** place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by rheumatoid arthritis. The diagnosis depends upon careful assessment of the distribution of the joints affected, the pattern of other joint problems or by finding the associated condition (e.g. psoriasis, see p. 1207).

Hallux valgus

The great toe migrates laterally. In the congenital form, the first metatarsal bone is displaced medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

Hallux rigidus

Osteoarthritis of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus: a stiff, dorsiflexed and painful great toe. Careful choice of footwear and the help of a podiatrist suffice for most cases, but some require surgery.

Metatarsalgia

This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. Rheumatoid arthritis causes misalignment of the metatarsal bones and severe metatarsalgia.

Treatment is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.

Morton's metatarsalgia is due to a neuroma, usually between the third and fourth metatarsal heads. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushioned-soled shoes. Occasionally a steroid injection or excision is necessary.

Stress (march) fractures

These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed. A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices. There is a possibility of osteoporosis.

Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve at the medial malleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel's sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

Pain under the heel

Plantar fasciitis is an enthesitis at the insertion of the tendon into the calcaneum. It produces localized pain under the heel when standing and walking, and local tenderness. It occurs alone or in spondyloarthritis.

Plantar spurs are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.

Calcaneal bursitis is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Whatever the cause, the pain is always worse in the morning as soon as weight is placed on the foot.

All of these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A dorsiflexion splint at night to stretch the plantar fascia is worth trying. When an injection is necessary, a medial approach is used, rather than through the heel pad, often under ultrasound guidance.

Pain behind the heel and leg

Sever's disease is a traction apophysitis of the Achilles tendon in young people (cf. Osgood-Schlatter disease, p. 546).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate spondyloarthritis. Raising the shoe heel reduces pain. Occasionally a low-pressure corticosteroid injection near the enthesis is necessary.

Achilles tendonitis causes a painful, tender swelling a few centimetres above the tendon's insertion. Advise against walking barefoot and jumping. Tendon damage or rupture can occur with quinolone, e.g. ciprofloxacin therapy. Therapeutic ultrasound is helpful. (**Caution:** a local injection may cause the tendon to rupture.) Autologous platelet concentrates are used but evidence for efficacy is poor.

Achilles bursitis lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes

The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment

syndromes can be acute and severe, such as following exercise.

In the anterior tibial syndrome there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

Pain in the chest

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma or osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see p. 527). In people with heart disease, costochondral pain may cause severe anxiety but it is not like angina and the patient should be reassured.

CHRONIC PAIN SYNDROMES

Chronic pain syndromes (see p. 1163) are difficult to manage. Psychological factors are at least as relevant as inflammation or damage in determining the patient's perception of pain. It is essential to be objective and non-judgemental when discussing physical, psychological and social factors without assuming which is primary. Chronic pain syndromes are difficult to explain scientifically. It is all too easy for a doctor to respond to this lack of a clear scientific cause by seeming to 'blame' the patient for the symptoms. Many chronic pain states are post-traumatic and some may be exacerbated partly by the process of litigation that may follow an injury.

Any chronic painful condition can change the way a person copes. Some people with chronic diseases or chronic pain cope well, but others adopt coping strategies and patterns of behaviour which make things worse. They become anxious, depressed or socially isolated, and their QoL is reduced. In chronic pain syndromes patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service.

Psychological states such as depression and anxiety produce physical symptoms, of which one is pain, while people with frank physical diseases are often understandably anxious and depressed. A biopsychosocial approach is best.

Chronic widespread pain (fibromyalgia)

Chronic widespread pain is defined as pain for more than three months both above and below the waist (p. 1163). It is a diagnosis of exclusion although it is still not universally accepted as a diagnosis. Multiple trigger points are reported by people with fibromyalgia (see p. 1163; Fig. 11.9). The pain is widespread, with unremitting, aching discomfort. Many patients have sleep disturbances, so they awake unrefreshed and have poor concentration. Multiple other symptoms, e.g. irritable bowel syndrome (IBS), tension headaches, dysmenorrhoea, atypical facial or chest pain, often co-exist. It occurs at any age and affects women more than men (7:1).

Doctors sometimes inappropriately label these patients 'heart sink' patients and patients sense this. The patient's

Chronic pain syndromes

Callus forming around a stress fracture of the second metatarsal at 4 weeks. X-rays initially were normal.

Figure 11.9 Trigger points in fibromyalgia.

frustration is compounded by the fact that most tests are normal, and they fear doctors believe it is 'all in their mind'. Sleep disturbance may lead to abnormalities of serotonin, substance P and cortisol levels. This is best regarded as a 'wind up' or pain amplification syndrome and is attributable to changes in the descending inhibitory pathways and in the spinal cord, resulting in a maladaptive pain response.

Treatment (see p. 1163)

A sympathetic, psychosocial, multidisciplinary approach is appropriate. A graded, supervised aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated. Cognitive behavioural therapy can help the person to pace their life more effectively and to cope better, although patients often resist referral for psychological help.

Drugs

Analgesics (e.g. paracetamol or weak opioids), help, and pregabalin and antidepressant drugs, such as fluoxetine, help when depression is a major factor.

Low-dose amitriptyline or dosulepin help sleep disturbance when taken a few hours before bedtime. They act by increasing the levels of serotonin (5HT) in the CNS and probably increasing descending sensory inhibition. It should be explained that these doses are analgesic and not antidepressant, and their side-effects should be outlined.

Trigger-point injections with local anaesthetic, corticosteroids or acupuncture are sometimes helpful. Oral corticosteroids are not helpful.

Chronic fatigue syndrome

Diffuse muscular pain and stiffness is common in this condition, which is described on page 1162.

Chronic (work-related) upper-limb pain syndrome

This name is preferred to 'repetitive strain injury' (RSI). The predominant symptoms are pain in all or part of one or both

arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and in musicians. When it arises at work, it is often at a time of changing work practices, shortage of staff or disharmony. Middle managers find it difficult to deal with and this compounds the stress.

It is seen throughout the developed world. It peaked in incidence in Australia in the 1970s and 1980s but has largely disappeared there, apparently because of changes in work practices, improvements in early medical management, changes in workers' compensation legislation, and reduced media discussion of the problem.

Treatment

If possible, there should be a brief period off work and a gradual return to activity as the pain settles. Use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or pregabalin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

Temporomandibular pain dysfunction syndrome

This is a disorder of the temporomandibular joint associated with nocturnal tooth grinding or abnormalities of bite. It occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are made worse by unnecessary dental treatment.

Hypermobility and hypermobility syndrome

Many people in the adult population have hypermobile joints (see p. 546). A small proportion are more prone to joint pains, joint instability and autonomic disturbances. This sometimes causes extreme anxiety and manifests as a chronic pain syndrome. Specific exercises to stabilize the joints, recognition of the problem and, sometimes, cognitive behavioral therapy all help. Surgery is best avoided because of problems with healing.

Chronic regional pain syndrome type I (previously called reflex sympathetic dystrophy or Sudeck's atrophy)

This is defined as 'a complex disorder or group of disorders that may develop as a consequence of trauma affecting the limbs, with or without obvious nerve lesions'. It may also develop after central nervous system lesions (e.g. strokes) or without cause. Its features are pain and other sensory abnormalities, including hyperaesthesia, autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating, and motor system abnormalities. This leads to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and

sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase, with pain, swelling and increased skin temperature, is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is initially clinical – a high index of suspicion and recognizing the unusual distribution of the pain. A three-phase bone scan shows diffuse or patchy increase in uptake in the affected limb in all three phases. MRI also shows these early changes. Demineralization on X-ray occurs later.

Treatment

Management is difficult and the problem often very disabling. The evidence base for treatment is poor. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs, corticosteroids and pregabalin or gabapentin are used in the early phase, together with active exercise of the limb encouraged by a physiotherapist. Intravenous disodium pamidronate can be used at this stage. Referral to a specialist pain clinic is essential. A stellate ganglion block may help upper limb involvement and a sympathetic chain block for the lower limb. Guanethidine (an alpha-blocking agent) or lidocaine administered to the limb under tourniquet are also used.

Chronic regional pain syndrome type II

This is discussed on [page 1067](#).

Analgesic and anti-inflammatory drugs for musculoskeletal problems

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and constantly to review their appropriateness. [Box 11.3](#) shows the main drugs available.

Simple and compound analgesic agents

Simple agents such as paracetamol, aspirin, or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine or morphine derivatives, should be used only with severe pain.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see [Fig. 15.30](#)). There are two specific cyclo-oxygenase enzymes:

- **COX-1** is the constitutive form present in many normal tissues.
- **COX-2** is the form mainly induced in response to pro-inflammatory cytokines and not found in most normal tissues (except the kidney). It is associated with oedema and the nociceptive and pyretic effects of inflammation.

Box 11.3 Analgesics and NSAIDs

Analgesics (in order of potency)

Advise that they be taken only if needed. Maximum doses are indicated here:

Paracetamol	500–1000 mg	6-hourly
Paracetamol (500 mg) and codeine (8–30 mg)	1–2 tablets	6-hourly
Dihydrocodeine	30–60 mg	Every 6–8 h
Paracetamol with dihydrocodeine	1–2 tablets	Every 6–8 h

Non-steroidal anti-inflammatory drugs (NSAIDs)

Always to be taken with food. Use slow-release preparations in inflammatory conditions or if more regular pain control is needed. Examples are:

Ibuprofen	200–400 mg	Every 6–8 h
Ibuprofen slow release	600–800 mg	12-hourly
Diclofenac	25–50 mg	8-hourly
Diclofenac slow release	75–100 mg	× 1–2 daily
Naproxen	250 mg	× 3–4 daily
Naproxen slow release	550 mg	× 2 daily
Celecoxib ^a	100–200 mg	× 2 daily

^aCOX-2-specific NSAID (coxib).

Effects and side-effects

Most of the older NSAIDs are nonspecific and block both enzymes but with variable specificity ('nonspecific NSAIDs' or nsNSAIDs). Their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1. COX-1 protects the gastric mucosa and blocking it accounts for the majority of upper gastrointestinal side-effects.

The most common side-effects with nonspecific NSAIDs are indigestion or skin rashes. More serious upper gastrointestinal side-effects are gastric erosions and peptic ulceration with perforation and bleeding. These occur more frequently in the elderly, in whom mortality is higher, in long-term use, and in those with high risk factors: a history of ulcers, *Helicobacter pylori*, and concurrent corticosteroids or anticoagulant therapy. Ibuprofen, in combination with low-dose aspirin, significantly increases the risk of severe gastrointestinal bleeding. Practice guidelines recommend proton pump inhibitors in high-GI-risk patients on nonspecific NSAIDs. H₂ blockers are less effective as gastroprotective agents. Prostaglandin E₂ analogues, e.g. misoprostol, reduce ulcer complications and are popular but may cause nausea and diarrhoea. Lower gastrointestinal (GI) side-effects of nonspecific NSAIDs are becoming more common.

COX-2 inhibitors ('Coxibs') produce fewer gastrointestinal side-effects but they still occur. Coxibs are used in patients who have a high risk of gastrointestinal disease and with no cardiovascular risk. People with a high risk of both may be better off taking an NSAID (ibuprofen or naproxen) or a Coxib with a proton pump inhibitor.

Coxibs and NSAIDs may reduce renal function, especially in the elderly (see [Box 12.3, p. 608](#)) and rarely cause cardiovascular events.

Uses

- **Short courses** of NSAIDs or coxibs are used in musculoskeletal pain and in osteoarthritis and

spondylosis but simple analgesia is often more appropriate.

- **In crystal synovitis**, NSAIDs and coxibs have a true anti-inflammatory effect (see p. 511).
- **In chronic inflammatory synovitis**, NSAIDs and coxibs do not alter the chronic inflammatory process, or decrease the risk of joint damage, but they do reduce pain and stiffness.
- Slow-release preparations are useful for inflammatory arthritis and when more constant pain control is needed.
- Be aware of the patient's gastrointestinal and cardiac risks before prescribing NSAIDs or coxibs.
- NSAID gels have some value in chronic arthritis.

OSTEOARTHRITIS (OA)

Osteoarthritis is the most common type of arthritis. It occurs with a variety of patterns in synovial joints and is characterized by cartilage loss with an accompanying periarticular bone response. It is probably not a single disease entity but a multifactorial process in which mechanical factors have a central role. The whole joint structure including cartilage, subchondral bone, ligaments, menisci, synovium and capsule is involved. Pathologically, there is significant inflammation of articular and periarticular structures and alteration in cartilage structure. Osteoarthritis is the subject of intense investigation but no drugs which halt or reverse this process have yet been developed.

Epidemiology

The prevalence of OA increases with age; it is uncommon below the age of 50 years and most people over 60 years will have some radiological evidence of it, although only a quarter of these will be symptomatic. It occurs worldwide, but with a variable distribution, e.g. in Asians, hip OA is less common and knee OA is more common than in Europeans. Women over 55 years are affected more commonly than men of a similar age. There is a familial pattern of inheritance in nodal OA and in primary generalized OA. OA has a variable distribution (Fig. 11.10). The resulting disabilities have major socioeconomic resource implications, particularly in the developed world. OA is the most common cause of disability in the Western world in older adults.

Aetiology (Box 11.4)

The gene that encodes collagen type II (*COL2A1*) is a candidate gene for familial OA but there is no single gene that associates with all patterns of OA. Abnormal local mechanical factors which affect loading and wear, such as prior injury, instability, hypermobility and joint dysplasia, play a role in most types of OA. Inflammation starting at periarticular entheses is seen during the inflammatory phase on MRI in nodal OA. Osteoarthritis is the result of active, sometimes inflammatory but potentially reparative processes rather than the inevitable result of trauma and ageing. Focal destruction of the articular cartilage is the common pathological feature. The spectrum of OA ranges from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease in which there is massive new bone formation at the joint margins.

Cartilage is a matrix of collagen fibres, which enclose a mixture of proteoglycans and water (see p. 494). The gene for human aggrecan has been cloned, and polymorphisms of the gene have been correlated with OA of the hand in older men.

Figure 11.10 Typical distribution of affected joints in (a) primary generalized OA and (b) pyrophosphate arthropathy; dark blobs, more commonly affected; pale blobs, less commonly affected.

Box 11.4 Factors predisposing to osteoarthritis

- **Obesity:** Predicts later risk of radiological and symptomatic OA of the hip and hand in population studies
- **Heredity:** Familial tendency to develop nodal and generalized OA
- **Gender:** Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones
- **Hypermobility** (see p. 546): Increased range of joint motion and reduced stability lead to OA
- **Osteoporosis:** There is a reduced risk of OA
- **Diseases:** See Table 11.12
- **Trauma:** A fracture through any joint. Meniscal and cruciate ligament tears cause OA of the knee
- **Congenital joint dysplasia:** Alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA
- **Joint congruity:** Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes' disease; osteonecrosis of the femoral head (see p. 556) in children and adolescents causes early-onset OA
- **Occupation:** Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip
- **Sport:** Repetitive use and injury in some sports causes a high incidence of lower-limb OA.

Cartilage is smooth-surfaced and shock-absorbing. Under normal circumstances, there is a dynamic balance between cartilage degradation by wear and its production by chondrocytes. Early in the development of OA, this balance is lost and, despite increased synthesis of extracellular matrix, the cartilage becomes oedematous. Focal erosion of cartilage develops. Chondrocytes die and, although repair is attempted from adjacent cartilage, the process is disordered. Eventually

Bijlsma JW, Berenbaum F, Lafeber FP. Osteoarthritis: an update with relevance for clinical practice. *Lancet* 2011; 377: 2115–2126.

Figure 11.11 Early osteoarthritis of a knee (diagram and X-ray). There is a medial compartment narrowing owing to cartilage thinning with subarticular sclerosis and marginal osteophyte formation (arrows).

the synthesis of extracellular matrix fails and the surface becomes fibrillated and fissured. Cartilage ulceration exposes underlying bone to increased stress, producing microfractures and cysts. The bone attempts repair but produces abnormal sclerotic subchondral bone and overgrowths at the joint margins, called osteophytes (Fig. 11.11). There is some secondary inflammation.

Pathogenesis

Several mechanisms have been suggested:

- **Abnormal stress and loading** leading to mechanical cartilage damage play a role in secondary OA.
- **Obesity** is a risk factor for developing OA of the hand and knee, but not the hip in later life. Increased skeletal mass increases cartilage volume.
- **Collagenases** (MMP-1 and MMP-13) cleave collagen, and other metalloproteinases such as stromelysin (MMP-3) and gelatinases (MMP-2 and MMP-9) are also present in the extracellular matrix. MMPs are secreted by chondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans around chondrocytes.
- **Tissue inhibitors of metalloproteinases** (TIMPs) regulate the MMPs. Disturbance of this regulation

may lead to an increase in cartilage degradation over synthesis and contribute to the development of OA. TIMPs have not yet proven to be of therapeutic value.

- **Osteoprotegerin (OPG), RANK and RANK ligand** (RANKL) control the remodelling of subchondral bone remodelling. Their levels are significantly different in OA chondrocytes. Inhibiting RANKL may prove a new therapeutic approach in OA.
- **Aggrecanase** production is stimulated by pro-inflammatory cytokines and aggrecan (the major proteoglycan) levels fall.
- **Synovial inflammation** is present in OA, and CRP in the serum may be raised. Interleukin-1 (IL-1) and tumour necrosis factor (TNF- α) release stimulates metalloproteinase production and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved. Anticytokine therapy has not yet been tested in OA. The production of cytokines by macrophages and of MMPs by chondrocytes in OA are dependent on the transcription factor NF- κ B. Inhibition of NF- κ B may have a therapeutic role in OA.
- **IL-1 receptor antagonist** genes are associated with radiographic severity of knee OA.
- **Growth factors**, including insulin-like growth factor (IGF-1) and transforming growth factor (TGF- β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair. However, increased TGF- β may cause increased subchondral bone density.
- **Cartilage breakdown products** lead to macrophage infiltration and vascular hyperplasia and IL1- β and TNF- α may contribute to further cartilage degradation.
- **Vascular endothelial growth factor** (VEGF) from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage.
- **Mutations** in the gene for type II collagen (*COL2A1*) have been associated with early polyarticular OA.
- **A strong hereditary element** underlying OA is suggested by twin studies. Further studies may reveal genetic markers for the disease. The influence of genetic factors is estimated at 35–65%.
- **In the Caucasian population** there is an inverse relationship between the risk of developing OA and osteoporosis.
- **Gender.** In *women*, weight-bearing sports produce a two- to three-fold increase in risk of OA of the hip and knee. In *men*, there is an association between hip OA and certain occupations: farming and labouring. OA may flare after the female menopause or after stopping hormone replacement therapy.
- **Periarticular enthesitis** has been proposed as a factor in the pathogenesis of nodal generalized OA (NGOA; p. 515) and is the subject of investigation.

The term *primary* OA is sometimes used when there is no obvious known predisposing factor.

Box 11.4 shows some of the predisposing factors for the development of OA, and Table 11.12 shows other conditions that sometimes cause secondary arthritis.

Clinical features

Osteoarthritis affects many joints, with diverse clinical patterns. Hip and knee OA are major causes of disability. Early OA is rarely symptomatic unless accompanied by a joint

Table 11.12 Causes of osteoarthritis

Primary OA	No known cause
Secondary OA	Pre-existing joint damage: Rheumatoid arthritis Gout Spondyloarthritis Septic arthritis Paget's disease Avascular necrosis, e.g. corticosteroid therapy Metabolic disease: Chondrocalcinosis Hereditary haemochromatosis Acromegaly Systemic diseases: Haemophilia – recurrent haemarthrosis Haemoglobinopathies, e.g. sickle cell disease Neuropathies

Table 11.13 Features of nodal OA

Familial Has a higher incidence in women Typical pattern of polyarticular involvement of the hand joints Develops in late middle age and around female menopause Has a generally good long-term functional outcome Associated with OA of the knee, hip and spine (NGOA)
--

effusion, whilst advanced radiological and pathological OA is not always symptomatic.

Some flare-ups are due to inflammation and there may be a slight rise in ESR or CRP. Focal synovitis is caused by fragments of shed bone or cartilage. Radiological OA is usually, but not inevitably, progressive. This progression may be stepwise or continual. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

Symptoms

- Joint pain
- Short-lived morning joint stiffness
- Functional limitation.

Signs

- Crepitus
- Restricted movement
- Bony enlargement
- Joint effusion and variable levels of inflammation
- Bony instability and muscle wasting.

Clinical subsets

Localized OA

Nodal OA (Table 11.13)

Joints of the hand are usually affected one at a time over several years, with the distal interphalangeal joints (DIPs) being more often involved than the proximal interphalangeal joints (PIPs). Nodal OA often starts around the female menopause. The onset may be painful and associated with tenderness, swelling and inflammation and impairment of hand function. At this stage, enthesitis can be seen on MRI. An intra-articular corticosteroid injection can be used at this stage, if deemed necessary. The inflammatory phase settles

Figure 11.12 Severe nodal osteoarthritis. The DIP joints demonstrate Heberden's nodes (arrows). The middle finger DIP joint is deformed and unstable. The thumb is adducted and the bony swelling of the first carpometacarpal joint is clearly shown – 'the squared hand of nodal OA'.

after some months or years, leaving painless bony swellings posterolaterally: Heberden's nodes (DIPs) and Bouchard's nodes (PIPs), along with stiffness and deformity (Fig. 11.12). Functional impairment is slight for most, although PIP osteoarthritis restricts gripping more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Thumb base OA co-exists with nodal OA and causes pain and disability, which decrease as the joint stiffens. The 'squared' hand in OA (Fig. 11.12) is caused by bony swelling of the carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

Hip OA

Hip OA (see p. 494) affects 7–25% of adult Caucasians but is significantly less common in black African and Asian populations. There are two major subgroups defined by the radiological appearance. The most common is *superior-pole hip* OA, where joint space narrowing and sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This is most common in men and unilateral at presentation, although both hips may become involved because the disease is progressive. Early onset of hip OA is associated with acetabular dysplasia or labral tears. Less commonly, *medial cartilage* loss occurs. This is most common in women and associated with hand involvement (nodal generalized OA – NGOA), and is usually bilateral. It is more rapidly disabling.

Knee OA

The prevalence of symptomatic knee OA is 40% in individuals aged over 75 years. It is commoner in women than in men. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with nodal OA

of the hand in elderly women, or as part of generalized OA. The medial compartment is most commonly affected and leads to a varus (bow-legged) deformity. There is often also retropatellar OA. Previous trauma, meniscal and cruciate ligament tears are risk factors for developing knee OA. Bone marrow lesions seen on MRI predict disease progression and eventual joint replacement.

Primary generalized OA

This is rare but is usually seen in combination with nodal OA – NGOA. The other joints affected are the knees, first MTP, hip, and intervertebral (spondylosis). Its onset is often sudden and severe. There is a female preponderance and a strong familial tendency. Periarticular ligamentous pathology may have an important role in the phenotypic expression of NGOA.

Erosive OA

This is rare. The DIPs and PIPs are inflamed and equally affected and the functional outcome is poor. Radiologically, there is marked osteolysis. Destructive phases are followed by phases of remodelling.

Crystal-associated OA

This is most commonly seen with calcium pyrophosphate deposition in the cartilage (chondrocalcinosis). *Chondrocalcinosis* increases in frequency with age and is seen on over 40% of knee X-rays in the over-80s, but is usually asymptomatic. The joints most commonly affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage, see Fig. 11.10). There is patchy linear calcification on X-ray (Fig. 11.13).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe chondrocalcinosis. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays. The joints affected differ from NGOA, being predominantly the knees, then wrists and shoulders. Chondrocalcinosis is associated with pseudogout, an acute crystal-induced arthritis (see p. 532).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips and knees, is associated with finding crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

Figure 11.13 Chondrocalcinosis of the knee. Note the linear calcification in the hyaline cartilage and calcification of the lateral meniscus (plus mild secondary OA).

Investigations in OA

- **Blood tests.** There is no specific test; the ESR is normal although high sensitivity CRP may be slightly raised. Rheumatoid factor and antinuclear antibodies are negative.
- **X-rays** are abnormal only when the damage is advanced. They are useful in preoperative assessments. For knees, a standing X-ray (stressed) is used to assess cartilage loss and 'skyline' views in flexion for patello-femoral OA.
- **MRI** demonstrates meniscal tears, early cartilage injury and subchondral bone marrow changes (osteochondral lesions).
- **Arthroscopy** reveals early fissuring and surface erosion of the cartilage.
- **Aspiration of synovial fluid** (if there is a painful effusion) shows a viscous fluid with few leucocytes (p. 498).

Management

The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than is radiological severity in OA of the knee. Education of the individual about the disease and its effects reduces pain, distress and disability and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

Physical measures

Weight loss and exercises for strength and stability are useful. Hydrotherapy helps, especially in lower-limb OA. Local heat, ice packs, massage and rubefacients or local NSAID gels are all used. Insoles for flat feet and a walking stick held on the contralateral side to the affected lower limb joint are useful.

There is increasing evidence that acupuncture helps knee OA. Other forms of complementary medicine are commonly used and, despite lack of scientific evidence, little is lost in trying it since a number of patients do seem to be helped.

Medication

Balance the potential benefit against potential side-effects, especially in the elderly. Paracetamol is effective and should be prescribed before NSAIDs (Box 11.3). NSAIDs or coxibs should be used intermittently when possible. Opioids should be used cautiously in older patients.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided. The role of intra-articular hyaluronan preparations is unclear.

Glucosamine and chondroitin (sold as food supplements) have no clinically relevant effect on joint pain or joint space narrowing.

There are no proven agents which halt or reverse OA, although they are greatly needed. The role of bisphosphonates in reducing bone changes is unclear. The role of drugs which block tissue metalloproteinases or cytokines (see pathogenesis, below) is also unclear.

Surgery

Arthroscopy for knee OA is not beneficial. However, replacement arthroplasty has transformed the management of severe OA. The safety of hip and knee replacements is now equal, with a complication rate of about 1%; loosening, and late blood-borne infection are the most serious. The slight but definite risks make it essential that the patient

is certain that surgery is necessary. Resurfacing hip surgery has become popular but may have higher complication rates in women. Unicompartmental knee replacement is a less major procedure and appropriate for some patients. For the vast majority, a total hip or knee replacement reduces pain and stiffness, greatly increases function and mobility, and – particularly significant for the elderly – independence.

Other surgical procedures include realignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

INFLAMMATORY ARTHRITIS

Inflammatory arthritis (Table 11.14) includes a large number of arthritic conditions in which the predominant feature is synovial inflammation (Box 11.5). This disparate group includes post-viral arthritis, rheumatoid arthritis, spondyloarthritis, crystal arthritis, and Lyme arthritis. The diagnosis of these conditions is helped by the pattern of joint involvement (symmetrical or asymmetrical; large or small) (Table 11.14), along with any non-articular disease; a past and family history is helpful. The periodicity of the arthritis (single acute, relapsing, chronic and progressive) also helps in the diagnosis.

Certain non-articular diseases, e.g. psoriasis, iritis, inflammatory bowel disease, nonspecific urethritis or recent dysentery, suggest spondyloarthritis. There may be evidence of recent viral illness (rubella, hepatitis B or erythrovirus), of rheumatic fever, or a tick bite and skin rash (Lyme disease). In early arthritis, it may not be possible to make a specific diagnosis until the disease has evolved from an undifferentiated arthritis into a chronic form.

There is a distinct genetic separation of rheumatoid-pattern synovitis and spondyloarthritis; RA (see below) is associated with a genetic marker in the class II major

histocompatibility genes, whilst spondyloarthritis shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 526).

In general, the pain and stiffness of inflammatory arthritis are worse in the morning often for several hours, in contrast to the much shorter morning stiffness of OA. Inflammatory markers (ESR and CRP) are often raised in inflammatory arthritis, and there is often a normochromic, normocytic anaemia. Specific types of arthritis are discussed below.

Early inflammatory polyarthritis

Undifferentiated polyarthritis requires urgent referral to a rheumatologist for diagnosis and treatment, including the early introduction of disease-modifying agents when indicated (see p. 523). In persistent inflammatory arthritis sustained remission depends on rapid diagnosis and intensive treatment. Poor prognostic features for undifferentiated polyarthritis are:

- Polyarticular onset
- Positive anticyclic citrullinated peptide antibodies
- Positive rheumatoid factor
- Joint erosion on X-ray at presentation
- Disease >3–6 months

RHEUMATOID ARTHRITIS (RA)

Rheumatoid arthritis is an autoimmune disease associated with autoantibodies to the Fc portion of immunoglobulin G (rheumatoid factor) and to citrullinated cyclic peptide. There is persistent synovitis, causing chronic symmetrical polyarthritis and systemic inflammation. Genetic studies suggest that RA is a heterogeneous group of diseases. Before the modern drug era it was rapidly disabling for most patients.

Epidemiology

RA has a worldwide distribution and affects 0.5–1% (with a female preponderance of 3:1) of the population. The prevalence is low in black Africans and Chinese people. The incidence is falling. RA remains a significant cause of disability and mortality and carries a high socioeconomic cost. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

Aetiology and pathogenesis

The cause is multifactorial and genetic and environmental factors play a part.

- **Gender.** Women before the menopause are affected three times more often than men. After the menopause, the frequency of onset is similar between the sexes, suggesting an aetiological role for sex hormones. A meta-analysis of the use of the oral contraceptive pill has shown no effect on RA overall, but it may delay the onset of disease.
- **Familial.** The disease is familial with an increased incidence in first-degree relatives and a high concordance amongst monozygotic twins (up to 15%) and dizygotic twins (3.5%). In occasional families it affects several generations.
- **Genetic** factors account for about 60% of disease susceptibility. There is a strong association between susceptibility to RA and certain HLA haplotypes: HLA-DR4, which occurs in 50–75% of patients and

2. Spondyloarthritis (associated with HLA-B27)
3. Metabolic arthritis (e.g. associated with crystals)

correlates with a poor prognosis, as does possession of certain shared alleles of HLA-DRB1*04. The possession of these shared epitope alleles in HLA-DRB1 (S2 and S3P) increases susceptibility to RA and may predispose to anti-citrullinated peptide antibodies (ACPA).

Citrullination is a process which modifies antigens, allowing them to fit into the shared epitope on HLA alleles. In a genome-wide association study in ACPA-positive RA, an association was found with loci near HLA-DRB1 and PTPN22 in people of European descent. These genes affect the presentation of autoantigens (HLA-DRB1), T cell receptor signal transduction (PTPN22) and targets of ACPA (PAD14).

- **Smoking** is an environmental risk factor for seropositive RA, possibly by activation of the innate immune system.

Immunology

RA is primarily a synovial disease which invades local tissues and rheumatoid synovitis results when chemoattractants produced in the joint recruit circulating inflammatory cells. Overproduction and overexpression of tumour necrosis factors (TNF) is a key inflammatory element in RA, leading to synovitis and joint destruction. Interaction of macrophages and T and B lymphocytes drives this overproduction. TNF- α stimulates overproduction of interleukin-6 and other cytokines. Antibodies to TNF- α and IL-6 or specific blocking agents produce marked short-term improvement in synovitis, indicating the pivotal role of these cytokines in the chronic synovitis (see p. 523). These antibodies also reduce the malaise and tiredness felt in active RA. Interleukin-1 plays a bigger role in certain subsets, such as systemic juvenile idiopathic arthritis (see p. 545) and adult-onset Still's disease (see p. 545).

An imbalance in the number of certain cell types appears to be central to immune regulation and its dysfunction.

- **Synovial cells** in chronic rheumatoid synovitis are predominantly abnormally behaving fibroblast-like synoviocytes, and macrophage-like synoviocytes which produce pro-inflammatory cytokines.
- **Abnormal fibroblast-like synoviocytes** appear to circulate between joints and may be the trigger for the polyarthritis.
- **Osteoclasts** play an active role in bone and cartilage destruction.
- **B cells** in the synovium, activated by cytokine-activated macrophages and T cells produce autoantibodies of which IgM and IgA RF is the most typical in RA. As RFs have the Fc portion of IgG as their antigen they have the potential for self aggregation and immune complex formation in the synovium. These may then trigger macrophages via IgGFC receptors to produce even more cytokines including IL-1, IL-8, TNF- α and granulocyte-macrophage colony-stimulating factor, and fibroblasts to produce IL-6.
- **CD20 positive B cell ablation** (a technique used for treating B cell lymphomas) induces temporary remission, reinforcing the central role of B cells in the chronic inflammation of RA. As the B cells return, the CRP rises and the disease flares again.
- **Synovial fibroblasts** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1: a molecule which supports B lymphocyte survival and differentiation), decay accelerating factor (DAF: a factor that prevents complement-induced cell lysis) and cadherin-II (which mediates cell to cell interactions).

These molecules may facilitate the formation of ectopic lymphoid tissue in synovium. Recent studies have shown that mice deficient in cadherin-II are resistant to a form of inflammatory arthritis. High-affinity antibodies are not a feature of RA, unlike other autoimmune diseases.

- **T cells** can be a part of the destructive process but other subsets reduce its severity. T cell-associated cytokines such as IL-2 and IL-4 are not present in high amounts and, when CD4-specific antibodies were used therapeutically to produce a specific helper T cell lymphopenia, they did not significantly alter the disease, suggesting that T cells play a lesser role. This treatment is no longer used. T17 helper cells (see p. 61), which produce IL-17A, 17F, 21 and 22 and TNF- α , may cause inflammation. The normal regulatory T cells are suppressed by TGP- β and interleukins (produced by macrophages and dendritic cells), allowing the T17 helper cells to increase.
- **The role of innate immunity** in RA pathogenesis and in predisposing the joint to inflammation are the subjects of increasing interest (see p. 51).

The *triggering antigen*, which leads to self-maintained inflammation in RA, remains unclear. Triggers for ACPA production include filaggrin, type II collagen and vimentin. There is little evidence that collagen type II is the triggering antigen, although it is a cause of arthritis in animal models of RA. Smoking is a potential trigger, particularly in ACPA-positive RA.

Pathology

Rheumatoid arthritis is typified by widespread persistent synovitis (inflammation of the synovial lining of joints, tendon sheaths or bursae). The normal synovium is thin and comprises a lining layer a few cells thick containing fibroblast-like synoviocytes and macrophages overlying loose connective tissue. The synoviocytes play a central role in synovial inflammation. In RA the synovium becomes greatly thickened and causes 'boggy' swelling around the joints and tendons. There is proliferation of the synovium into folds and fronds, and it is infiltrated by a variety of inflammatory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. There are disorganized lymphoid follicles. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (Fig. 11.14). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions that contain lymphocytes and dying polymorphs.

The hyperplastic synovium spreads from the joint margins on to the cartilage surface. This 'pannus' of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

Fibroblasts from the proliferating synovium also grow along the course of blood vessels between the synovial margins and the epiphyseal bone cavity and damage the bone. This is shown by MRI to occur in the first 3–6 months following onset of the arthritis, and before the diagnostic, ill-defined juxta-articular bony 'erosions' appear on X-ray (Fig. 11.15). This early damage justifies the use of DMARDs (see p. 523) within 3–6 months of onset of the arthritis. Low-dose steroids delay and anti-TNF- α agents halt and

occasionally reverse erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.

Rheumatoid factors (RFs) and anti-citrullinated peptide antibodies (ACPAs)

RFs (see p. 496) are circulating autoantibodies that have the Fc portion of IgG as their antigen. Transient production of RF is an essential part of the body's normal mechanism for removing immune complexes, but in RA they show a much higher affinity and their production is persistent and occurs in the joints. They are of any immunoglobulin class (IgM, IgG or IgA), but the most common tests employed clinically detect IgM rheumatoid factor. Around 70% of people with polyarticular RA have IgM rheumatoid factor in the serum. Positive titres can predate the onset of RA.

The term 'seronegative RA' is used for patients in whom the standard tests for IgM rheumatoid factor are persistently negative. They tend to have a more limited pattern of synovitis.

IgM rheumatoid factor is not diagnostic of RA and its absence does not rule the disease out; however, it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage and greater disability eventually, and justifies earlier use of DMARDs.

Anti-CCP antibodies (ACPA) (p. 497) are usually present with RF in RA. They are better predictors of a transition from

Figure 11.15 X-ray of early RA, showing typical erosions at the thumb (black and white arrows) and middle MCP joints (black arrow) and at the ulnar styloid (white arrow).

early transient inflammatory arthritis to persistent synovitis and early RA. RF and the ACPA together are even more specific.

Clinical features of RA

Typical presentation

The most typical presentation of rheumatoid arthritis (approximately 70% of cases) begins as a slowly progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months. The patient is usually between 30 and 50 years of age, but the disease can occur at any age. Less commonly (15%) a rapid onset can occur over a few days (or explosively overnight) with a severe symmetrical polyarticular involvement, especially in the elderly. Factors which indicate a poor prognosis are listed in [Box 11.6](#). The differential diagnosis of early RA is shown in [Box 11.7](#).

Older classification criteria used to distinguish RA from other forms of arthritis (American College of Rheumatology, ACR criteria 1987) are now mainly used to ensure matched groups for research. The newer criteria that have replaced them are more suitable for assessing early arthritis because they do not rely on later changes such as erosions and extra-articular disease ([Box 11.8](#)).

In early RA, the combination of at least one swollen joint for more than 6 weeks with no prior injury and no associated history or family history of spondyloarthritis or associated conditions such as psoriasis (see p. 1207) and a positive ACPA test is the best way to select patients for earlier treatment to avoid joint damage. This earlier treatment is evidence based and has been shown to reduce the risk of the development of damage and thus reduce permanent joint deformities.

Box 11.6 Factors predicting poor prognosis for progression in early RA

- Age
- Female sex
- Symmetrical small joint involvement
- Morning stiffness >30 min
- >4 swollen joints
- CRP >20
- Positive RF and ACPA

- Acute nodal osteoarthritis (PIPs and DIPs involved)

Box 11.8 ACR/EULAR 2010 criteria for RA

Criteria	Points
1. Joint involvement	0–5
1 medium to large joint	0
2–10 medium to large joints	1
1–3 small joints (large joints not counted)	2
4–10 small joints (large joints not counted)	3
>10 joints at least one small joint	5
2. Serology	0–3
Negative RF and negative ACPA	0
Low positive RF or low positive ACPA	2
High positive RF or high positive ACPA	3
3. Acute-phase reactants	0–1
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
4. Duration of symptoms	0–1
<6 weeks	0
≥6 weeks	1

The cut-off point for RA is at 6 or more points. Patients can also be classified as having RA if they have both typical erosions and longstanding disease previously satisfying the classification criteria. (Adapted from Scott DL, Wolfe F, Huizinga TW. Rheumatoid arthritis. Lancet 2010; 376:1094–1108.)

ACR, American College of Rheumatology

Symptoms and signs

Early RA

The majority of patients complain of pain and stiffness of the small joints of the hands (metacarpophalangeal, MCP; proximal and distal interphalangeal, PIP, DIP) and feet (metatarsophalangeal, MTP). The wrists, elbows, shoulders, knees and ankles are also affected. In most cases, many joints are involved, but 10% present with a monoarthritis of the knee or shoulder or with carpal tunnel syndrome.

Fatigue is a common complaint. The pain and stiffness are significantly worse in the morning. Sleep is disturbed.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities and non-articular features develop if the disease cannot be controlled (see below).

RA in the older patient may mimic polymyalgia rheumatica; the synovitis becomes apparent as the corticosteroid dose is reduced.

Box 11.9 Presentations of rheumatoid arthritis

- **Palindromic:** Palindromic monoarticular attacks lasting 24–48 hours; 50% progress to other types of RA.
- **Transient:** A self-limiting disease, lasting less than 12 months and leaving no permanent joint damage. Usually seronegative for IgM rheumatoid factor and ACPA. Some of these may be undetected post-viral arthritis.
- **Remitting:** There is a period of several years during which the arthritis is active but then remits, leaving minimal damage.
- **Chronic, persistent:** The most typical form, it may be seropositive or seronegative for IgM rheumatoid factor. The disease follows a relapsing and remitting course over many years. Seropositive (plus ACPA) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.
- **Rapidly progressive:** The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus ACPA), has a high incidence of systemic complications and is difficult to treat.

Other presentations

The presentation and progression of RA is variable. Presentations are shown in Box 11.9. Relapses and remissions occur either spontaneously or on drug therapy. In some patients, the disease remains active, producing progressive joint damage. Rarely, the process may cease ('burnt-out RA').

Seronegative RA initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis, but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (p. 528).

Palindromic rheumatism is unusual (5%) and consists of short-lived (24–72 hours) episodes of acute monoarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% go on to develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue to have acute episodic arthritis. The detection of RF or ACPA predicts conversion to chronic, destructive synovitis.

Complications (Table 11.15)

Septic arthritis

This is a serious complication with significant morbidity and mortality. In immunosuppressed patients, the affected joints may not be hot and inflamed with accompanying fever. There is usually a neutrophil leucocytosis. Any effusion, particularly of sudden onset, should be aspirated. *Staphylococcus aureus* is the most common organism. Blood cultures are often positive. Treatment is with systemic antibiotics (see p. 533) and drainage.

Table 11.15 Complications of rheumatoid arthritis

Complications of the condition

Ruptured tendons
Ruptured joints (Baker's cysts)
Joint infection
Spinal cord compression (atlantoaxial or upper cervical spine)
Amyloidosis (rare)

Side-effects of therapy

See Table 11.16

Amyloidosis

Amyloidosis (see p. 1042) is found in a very small number of people with uncontrolled rheumatoid arthritis. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

Joint involvement in RA

The changes described below are seen in established disease or when early drug treatment has been ineffective.

Hands and wrists

The impact of RA on the hands is severe. In early disease, the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- **A combination of ulnar drift and palmar subluxation of the MCPs** (Fig. 11.16). This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled
- **Fixed flexion** (buttonhole or boutonnière deformity) or **fixed hyperextension** (swan-neck deformity) of the PIP joints, which impairs hand function
- **Swelling and dorsal subluxation of the ulnar styloid**, which leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

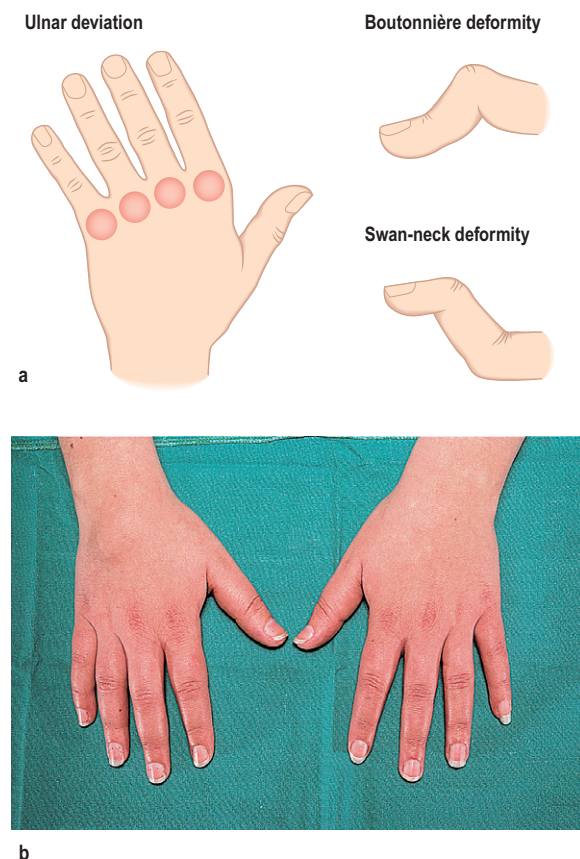

Figure 11.16 Rheumatoid arthritis. (a) Characteristic hand deformities in RA. (b) Early rheumatoid arthritis – dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

Shoulders

RA commonly affects the shoulders. Initially, the symptoms mimic rotator cuff tendonitis (see p. 500) with a painful arc syndrome and pain in the upper arms at night. As the joints become more damaged, global stiffening occurs. Late in the disease rotator cuff tears are common (see p. 501) and interfere with dressing, feeding and personal toilet.

Elbows

Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease, flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

Feet

One of the earliest manifestations of RA is painful swelling of the MTP joints.

- The foot becomes broader and a hammer-toe deformity develops.
- Exposure of the metatarsal heads to pressure by the forward migration of the protective fibrofatty pad (Fig. 11.17) causes pain.
- Ulcers or calluses may develop under the metatarsal heads and over the dorsum of the toes.
- Mid- and hindfoot RA causes a flat medial arch and loss of flexibility of the foot.
- The ankle often assumes a valgus position.

Appropriate broad, deep, cushioned shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

Knees

Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 507). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 508). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary

Figure 11.17 The toes in RA, showing exposure of the metatarsal heads with forward migration of the soft tissue pad.

OA follows. Total knee replacement is often the only way to restore mobility and relieve pain.

Hips

The hips are occasionally affected in early RA but are less commonly affected than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement is usually necessary.

Cervical spine

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae which separate the odontoid peg from the anterior arch of the atlas and from its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical vertebral instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the best way of visualizing this, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking which cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency.

Image the cervical spine in flexion and extension in people with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation.

Other joints

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

Non-articular manifestations (Fig. 11.18)

Soft tissue surrounding joints

Subcutaneous nodules are firm, intradermal and generally occur over pressure points, typically the elbows, the finger

joints and the Achilles tendon. Histologically, there is a necrotic centre surrounded by rows of activated macrophages, which resembles synovitis without a synovial space.

The nodules may ulcerate and become infected. They may resolve when the disease comes under control. The nodules can be removed surgically but they tend to recur.

The olecranon and other bursae may be swollen (bursitis).

Tenosynovitis of flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Corticosteroid-induced myopathy occurs. Osteoporosis is more common in poorly controlled RA.

Less common non-articular manifestations

Non-articular complications are becoming less common, probably because of more effective disease control.

Lungs (see p. 792)

- Airways disease: a spectrum from predominant bronchiectasis (cough and daily sputum) to predominant obliterative bronchiolitis (progressive breathlessness)
- Disease of the pleura: pleural effusion (asymptomatic to mildly breathless) and thickening
- Fibrosing alveolitis: a combination of inflammation and basal lung fibrosis
- Peripheral, intrapulmonary nodules: these are asymptomatic but may cavitate, especially with pneumoconiosis (Caplan's syndrome)
- Infective lesions, e.g. TB in patients on biological DMARDs.

Vasculitis

Vasculitis (see p. 542) is caused by immune complex deposition in arterial walls. It is uncommon. Smoking is a risk factor. Findings are:

- Nail-fold infarcts due to cutaneous vasculitis
- Widespread cutaneous vasculitis with necrosis of the skin (seen in people with very active, strongly seropositive disease)
- Mononeuritis multiplex (p. 1145)
- Necrotizing arteritis of the mesenteric vessels causing bowel infarction.

The heart and peripheral vessels

Poorly controlled RA with a persistently raised CRP and high cholesterol is a risk factor for premature coronary artery and cerebrovascular atherosclerosis independent of traditional risk factors (i.e. high cholesterol and hypertension). Other cardiovascular problems include:

- Pericarditis is rarely symptomatic.
- Endocarditis and myocardial disease, rarely symptomatic, are found at post-mortem in approximately 20% of cases.
- Raynaud's syndrome occurs (see p. 788).

The nervous system

- Peripheral sensory neuropathies: mononeuritis multiplex or symmetrical, peripheral – due to vasculitis of the vasa nervorum
- Compression neuropathies: carpal or tarsal tunnel syndrome – due to synovitis
- Cord compression: due to atlantoaxial subluxation (see above).

Figure 11.18 Non-articular manifestations of RA.

The eyes

- Sicca syndrome causes dry mouth and eyes (see Sjögren's syndrome, p. 541).
- Scleritis and episcleritis occur in severe, seropositive disease, resulting in painful red eye.
- Scleromalacia perforans (rare).

The kidneys

Amyloidosis causes proteinuria, nephrotic syndrome and chronic kidney disease. It occurs rarely in severe, longstanding rheumatoid disease and is due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs. SAP is an acute-phase reactant, produced normally in the liver.

The spleen, lymph nodes and blood

Felty's syndrome is splenomegaly and neutropenia in a patient with RA. Leg ulcers or sepsis are complications. HLA-DR4 is found in 95% of patients, compared with 50–75% of people with RA alone.

The lymph nodes may be palpable, usually proximal to affected joints. There may be peripheral lymphoedema of the arm or leg.

Anaemia is almost universal and is usually normochromic and normocytic. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs positive). There may be a pancytopenia due to hypersplenism in Felty's syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

Diagnosis and investigations

The diagnosis relies on the clinical features described above. The predictors of poor prognosis arthritis are listed in Box 11.6. Initial investigations include:

- **Blood count.** Normochromic, normocytic anaemia may be present.
- The **ESR** and/or **CRP** are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- **Serology.** ACPA (see p. 497) is present earlier in the disease (and may predate it by many years), and in early inflammatory arthritis indicates the likelihood of progressing to RA. Rheumatoid factor is present in approximately 70% of cases and ANA at low titre in 30%.
- **X-rays** show soft tissue swelling in early disease but MRI demonstrates synovitis and early erosions.
- **Aspiration of the joint** if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint septic arthritis should be suspected (see p. 532).
- **Doppler ultrasound** is a very effective way of demonstrating persistent synovitis when deciding on the need for DMARDs or assessing their efficacy.

Other investigations will depend on the clinical picture as outlined above. In severe disease, extensive imaging of joints may be required. MRI is the technique of choice, especially for the knee and cervical spine.

Management of RA (Box 11.10)

The diagnosis of RA inevitably causes concern and fear in the patient and requires a lot of explanation and reassurance. Most guidelines suggest that anyone with early inflammatory

Box 11.10 Management of rheumatoid arthritis

- Establish the diagnosis clinically.
- Use NSAIDs and analgesics to control symptoms.
- Try to induce remission with i.m. depot methylprednisolone 80–120 mg if synovitis persists beyond 6 weeks.
- If synovitis recurs, refer to a rheumatologist to start DMARDs and consider combinations of sulfasalazine, methotrexate and hydroxychloroquine. Give a second dose of i.m. depot methylprednisolone or oral steroids.
- Refer for physiotherapy and general advice through a specialist team.
- As improvement occurs, as measured by less pain, less morning stiffness and reduced acute-phase response, tail-off steroids and possibly reduce drugs.
- If no better – anti-TNF- α therapy or rituximab.

arthritis should be referred to a specialist arthritis clinic within 3 months of onset, whenever possible.

The doctor should have a positive approach and remind the patient that with the help of drugs most people continue to lead a more or less normal life, despite their arthritis; 25% will recover completely. The earliest years are often the most difficult and people should be helped and encouraged to stay at work during this phase if possible. Uncertainty about remissions and flares and the impact of drug treatment makes planning difficult. However, patients adjust remarkably with time and support; the specialist team in a rheumatology unit (including doctors, nurses, physiotherapists, podiatrists and psychologists) helps patients learn to cope. Leaflets, websites and local patient groups also provide helpful advice.

Patients from socially deprived backgrounds and smokers have a worse prognosis. Statins have been shown to be of benefit in reducing cardiovascular risk and possibly inflammation whatever the cholesterol level; more studies are required.

Drug therapy

There is no curative agent available for RA but drugs are now available that prevent disease deterioration. Symptoms are controlled with analgesia and NSAIDs. Data now support the use of DMARDs early in the disease to prevent the long-term irreversible damaging effects of inflammation of the joints, and drugs that block TNF- α and IL-1 and the use of B cell ablation with rituximab are revolutionizing the management of RA. Searching for persistent synovitis in patients in apparent remission using Doppler ultrasound is leading to more intensive therapeutic regimes which will potentially reduce longer-term disability.

Non-steroidal anti-inflammatory drugs (NSAIDs) and coxibs

Most people with RA are unable to cope without an NSAID to relieve night pain and morning stiffness. NSAIDs do not reduce the underlying inflammatory process. They all act on the cyclo-oxygenase (COX) pathway (see Fig. 15.30). The individual response to NSAIDs varies greatly. It is desirable therefore to try several different drugs for a particular patient in order to find the best (Box 11.13). Each compound should be given for at least a week. Start with an inexpensive NSAID with few side-effects and with which you are familiar. Regular doses are needed to be effective. The major side-effects of NSAIDs and the use of coxibs are discussed on page 511. If gastrointestinal side-effects are prominent, or the patient is

over 65 years of age, add a proton pump inhibitor. Slow-release preparations (e.g. slow-release diclofenac, 75 mg, taken after supper), or a suppository at bedtime, usually work well. For additional relief, a simple analgesic is taken as required (e.g. paracetamol or a combination of codeine or dihydrocodeine and paracetamol). Many patients need night sedation.

Corticosteroids

There is evidence to suggest that the early use of corticosteroids slows down the course of the disease but intensive short courses in very early arthritis do not appear to stop progressive disease. Corticosteroids are the commonest cause of secondary osteoporosis. Treatment for more than 3 months or with repeated courses is a risk, and concomitant calcium with vitamin D and bisphosphonates is necessary.

Intra-articular injections with semicrystalline steroid preparations have a powerful but sometimes only short-lived effect.

Intramuscular depot injections (40–120 mg depot methylprednisolone) help whilst waiting for DMARDs to work and to control severe disease flares, or they can be used before a holiday or other life event. They should be used infrequently.

Oral corticosteroids have a number of problems (Boxes 11.11 and 19.11). They are powerful disease-controlling drugs, but are avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are often used. Doses of 5–7.5 mg daily as maintenance therapy are used in some centres. Corticosteroids are invaluable to people with severe disease with extra-articular manifestations such as vasculitis.

Disease-modifying anti-rheumatic drugs (DMARDs)

DMARDs, prescribed by a rheumatologist, are listed in Table 11.16 (see also Fig. 11.19).

- Traditional DMARDs, which mainly act through cytokine inhibition, reduce inflammation, with a reduction of joint swelling, a fall in the plasma acute-phase reactants and slowing of the development of joint erosions and irreversible damage. Their beneficial effect is not immediate (hence 'slow-acting agents') and may be partial or transient.
- DMARDs often only have a partial effect, achieving between 20% and 50% improvement by ACR criteria for disease remission (Box 11.12).

Box 11.11 Problems associated with the use of corticosteroids

- Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks of the drugs themselves.
- Patients must be warned to avoid sugars and saturated fats and to eat less because of the risk of weight gain.
- The skin becomes thin and easily damaged.
- Monitor for diabetes and hypertension.
- Cataract formation may be accelerated.
- Osteoporosis develops within 6 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium and vitamin D and bisphosphonate (see this chapter).

DMARDs are used as early as possible once RA has been diagnosed. Studies suggest that early intervention with DMARDs at 6 weeks to 6 months improves the outcome. Combinations of three or four drugs (steroids, sulfasalazine, methotrexate and hydroxychloroquine) in early RA are increasingly common, reducing the number of agents once remission has been achieved. Most DMARDs are contraindicated in pregnancy (Box 11.13). Effective treatment with DMARDs reduces the increased cardiovascular risk seen in people with RA.

Sulfasalazine

This is a combination of sulfapyridine and 5-amino-salicylic acid. Sulfapyridine is probably the active component. It is well tolerated and can be used during pregnancy. Around 50% of patients respond in the first 3–6 months, but efficacy can be lost. Blood monitoring is obligatory because of the risk of leucopenia and thrombocytopenia.

Methotrexate

This is considered by many to be the 'gold standard' drug in RA. It should not be used in pregnancy. Conception should be delayed for 3–6 months off the drug for either partner. A chest X-ray is taken to exclude tuberculosis. An initial pneumococcal and annual influenza vaccination are given. The starting **weekly** dose of 2.5–7.5 mg orally is increased up to 15–25 mg if necessary. It is well tolerated and this therapy can be introduced early in the disease. Nausea or poor absorption may limit its efficacy, in which case it is given by subcutaneous injection. Oral folic acid reduces side-effects but may also reduce efficacy. Full blood counts and liver biochemistry should be monitored. It usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

Hydroxychloroquine

A dose of 200–400 g daily is well tolerated. It is used alone in mild disease or as an adjunct to other DMARDs. Retinopathy is extremely rare (occurring in about 1 in 2000 patients on this drug). Some rheumatologists arrange an initial check of macular function with an Amsler chart and further reviews annually, as retinopathy is irreversible.

Leflunomide

This DMARD exerts an immunomodulatory effect by preventing pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydroorotate dehydrogenase, thus blocking clonal expansion of T cells. Most other cells are able to bypass this blockade. It has a long half-life of 4–28 days. A dose of 20 mg daily (10 mg if diarrhoea is a problem) is used. Diarrhoea diminishes with time. Blood monitoring is obligatory (full blood count, platelets, liver biochemistry). The onset of action is 4 weeks with some further improvement sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate. Its long half-life means that it is best avoided in women planning a family.

Cytokine modulators

TNF- α blockers. The availability of agents that block TNF- α has significantly changed the traditional use of DMARDs. Because of their cost they are used after at least two DMARDs (usually sulfasalazine and methotrexate) have been tried. They represent a major therapeutic advance, although not all patients respond and there is loss of efficacy in some responders. They are usually given in combination with

methotrexate to reduce loss of efficacy due to antibody formation.

- **Etanercept** is a fully humanized p75 TNF- α receptor IgG1 fusion protein given by self-administered subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.
- **Adalimumab** is a fully human monoclonal antibody against TNF- α , given along with methotrexate.
- **Infliximab** is a monoclonal antibody against TNF- α , given intravenously and co-prescribed with methotrexate to prevent loss of efficacy because of antibody formation.
- **Certolizumab pegol** is an Fab fragment of a humanized TNF- α inhibitor monoclonal antibody approved in the UK and other countries. It is PEGylated, i.e. polyethylene glycol groups are added to reduce its immunogenicity and prolong its half-life. The lack of an Fc portion on the antibody aims to reduce the risk of

complement-dependent and antibody dependent cytotoxicity. It is useful with or without methotrexate for severe active RA.

- **Golimumab** is a human IgG1- κ monoclonal antibody against TNF which is awaiting approval in some countries. It is given by subcutaneous injection once monthly for severe RA.

These products slow or halt erosion formation in up to 70% of people with RA and produce healing in a few. Malaise and tiredness improve in a manner that is not seen with other DMARDs. Secondary failure occurs with all in the first year and changing to another anti-TNF agent is justified and often regains control of the disease. Potential biomarkers for responsiveness are being studied. Failure to respond to one does not predict failure to others.

Side-effects. Many patients on cytokine modulators are entered into a long-term observational study in the UK and other countries to monitor for potential side-effects. To date,

Table 11.16 Disease-modifying anti-rheumatic drugs (DMARDs)

Drug	Dose	Side-effects	Monitoring to detect side-effects
Sulfasalazine (enteric coated)	500 mg daily after food, increasing to 2–3 g daily	Nausea Skin rashes and mouth ulcers Neutropenia and/or thrombocytopenia Abnormal liver biochemistry	Initial, 2 weeks, 4 weeks, then 4-monthly As above
Methotrexate (give pneumovax and annual 'flu vaccination)	2.5 mg increasing to max. 25 mg weekly, orally or s.c.	Nausea, mouth ulcers and diarrhoea Abnormal liver biochemistry Neutropenia and/or thrombocytopenia Renal impairment Pulmonary fibrosis (rare)	Baseline chest X-ray Initial, 2 weeks, then 4–8-weekly
Leflunomide	10–20 mg daily. Occasionally with initial loading dose	Diarrhoea Neutropenia and/or thrombocytopenia Abnormal liver biochemistry Alopecia Hypertension	Initial, then 2-weekly; monthly at 6 months Initial, then 2-weekly; monthly at 6 months
Cytokine modulators			
TNF-α blockers		Below applies to all	
Etanercept (alone or with methotrexate)	S.C. 25 mg \times 2 weekly or 50 mg weekly	Injection site reactions Infections, e.g. TB and septicaemia	See British Society for Rheumatology Guidelines www.rheumatology.org.uk/guidelines/clinicalguidelines
Adalimumab (with methotrexate)	S.C. 40 mg alternate weeks	Hypersensitivity reactions Heart failure Rare – demyelination and autoimmune syndromes	NICE guidelines www.nice.org.uk Stop if no response after 6 months
Infliximab (with methotrexate)	i.v. 3–10 mg/kg every 4–8 weeks	Reversible lupus-like syndrome	See p. 524
Certolizumab pegol (alone or with methotrexate)	S.C. 400 mg in weeks 0, 2, 4, then 200 mg fortnightly	Infections, hypersensitivity reactions	Review treatment if no response by 12 weeks
Golimumab	S.C. monthly 50 mg	Same as cytokine modulators	See p. 524
Other biological agents (used with methotrexate)			
Rituximab	i.v. 500–1000 mg	Hypo/hypertension, skin rash, nausea, pruritus, back pain. Rare – toxic epidermal necrolysis	
Abatacept	i.v. 10 mg/kg on days 1, 15, 30 and then monthly	Nausea, vomiting Headache Hypersensitivity – rare	
Tocilizumab	i.v. 8 mg/kg infusion	Headache, skin eruption, stomatitis, fever, anaphylactic reactions	

Figure 11.19 American College of Radiology ACR50 responses in trials of DMARDs and biological agents (50% improvement in five of seven measures in the ACR 1987 criteria).^{a,b}

(a) ACR50 response in trials of DMARDs and biological agents.

(b) Impact of treatment duration, disease stage and prior treatment on ACR50 response. The difference between patients treated with active drug and placebo is greatest in people with late rheumatoid arthritis who have failed biological treatment and whose disease is managed for short periods. The difference is smallest in individuals with early arthritis who have not previously received DMARDs and are treated for a long time.

American College of Rheumatology 1987 criteria for diagnosis of RA (revised 1988) have been superseded (see Box 11.8) but are used in trials, with ≥ 4 criteria necessary for diagnosis: morning stiffness >1 hours for ≥ 6 weeks; arthritis of ≥ 3 joints for ≥ 6 weeks; arthritis of hand joints and wrists for ≥ 6 weeks; symmetrical arthritis, subcutaneous nodules; positive serum rheumatoid factor; typical radiological changes (erosions and/or periarticular osteopenia). Error bars 95% CIs. (From Scott DL, Wolfe F, Huizinga TW. Rheumatoid arthritis. *Lancet* 2010; 376:1094–1108, with permission.)

Box 11.12 ACR criteria for disease remission in rheumatoid arthritis

- Morning stiffness <15 min
- No fatigue, joint pain, joint tenderness or soft tissue swelling
- ESR <30 in women, <20 in men

Box 11.13 Drug use during pregnancy in treatment of rheumatoid arthritis

Paracetamol – the oral analgesic of choice

- **Oral NSAIDs and selective COX-2 inhibitors:** can be used after implantation up until the last trimester if symptoms justify their use.
- **Corticosteroids:** may be used to control disease flares (main maternal risks are hypertension, glucose intolerance and osteoporosis).
- **DMARDs:**
 - *May be used:* sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required to control inflammation.
 - *Must be avoided:* methotrexate, leflunomide, cyclophosphamide, gold and penicillamine. Women should not conceive while taking methotrexate or leflunomide.
- **Cytokine modulators:** safety during pregnancy is currently unclear.

Contraindicated in breast-feeding: methotrexate, leflunomide, cyclophosphamide, ciclosporin, azathioprine, sulfasalazine, hydroxychloroquine.

probably less common with etanercept. A pre-treatment chest X-ray is recommended, with a specialist review for high-risk groups. TB should be treated before using these agents and a course of prophylaxis is used in latent disease. There is an increased risk of chest infections which requires close monitoring. Hepatitis B and C infection requires careful risk analysis and regular aminotransferase monitoring if anti-TNF agents are prescribed. They should not be used in patients who have severe cardiac failure.

These agents are extremely expensive when compared with traditional DMARDs but they may save costs in the longer term by reducing disability and the need for hospitalization. Their use should be restricted to specialist centres. To date there is no evidence of an adverse effect on pregnancy outcome but care is essential.

Other cytokine modulators

Rituximab is a genetically engineered chimeric monoclonal antibody (p. 72) that causes lysis of CD20-positive B cells. CD20 is a pan-B cell surface antigenic phosphoprotein. Its expression is restricted to pre-B and mature B cells but it is not present on stem cells and is lost before differentiation into plasma cells. Rituximab produces significant improvement in RF-factor positive RA for 8 months to several years when used alone or in combination with corticosteroids and/or methotrexate. This is associated with a 6–9-month B cell lymphopenia with little change in circulating immunoglobulins. A re-flare is often accompanied by a return of peripheral lymphocytes and a rise in CRP. Rituximab can be reused as the disease flares. Repeated courses over up to 5 years are acceptable and well tolerated and around 80% of RF-positive patients respond with 50–60% showing persistent disease control. It is worth trying in patients who have failed to respond to anti-TNF agents. There may be an increased risk of chest infections, and immunoglobulin levels may fall progressively and need to be monitored.

Abatacept is a recombinant fusion protein of CTLA4 and the Fc portion of IgG1, which selectively modulates T cell

the results are reassuring. People with severe RA are at slightly increased risk of lymphoma and this is being carefully monitored. There is no convincing evidence of any increased risk of other cancers. A few people become ANA positive and develop a reversible lupus-like syndrome, leucocytoclastic vasculitis, some extracutaneous involvement or interstitial lung disease. Reactivation of old TB may occur but is

activation by costimulation blockade. It may have an important role in patients who do not respond to anti-TNF regimens.

Tocilizumab is a humanized monoclonal anti-IL-6 receptor antibody and is used with methotrexate for moderate to severe RA after at least one other cytokine modulator has failed.

Anakinra is a human recombinant IL-1 receptor antagonist which is used in combination with methotrexate. It has been used after anti-TNF agents have been unsuccessful, but is now only recommended for clinical studies.

Spleen tyrosine kinase (SYK) inhibitor given orally has been effective in RA in phase 2 studies.

Drugs used less commonly

Gold (sodium aurothiomalate) is given by deep intramuscular injection. A response (occasionally remission) is seen in about 3 months. Side-effects or lack of effect mean that few patients remain on it beyond 2 years. Blood and urine testing are mandatory.

D-Penicillamine is given before food for at least 3 months before improvement occurs. If proteinuria exceeds 2 g/24 hours the drug must be stopped. Loss of taste is reversible. Other rare side-effects include a lupus erythematosus-like syndrome and a myasthenia gravis-like syndrome.

Azathioprine at a maximum dose of 2.5 mg/kg and *cyclophosphamide* 1–2 mg/kg have been used, usually when other DMARDs have been ineffective. They are often used when extra-articular features are severe, particularly with vasculitis. There is a high risk of neutropenia and possibly liver toxicity from azathioprine in patients who have low levels of the enzyme thiopurine methyltransferase (TPMT) which metabolizes azathioprine into its active metabolites. Pretesting is a wise precaution.

Ciclosporin 2.5–4 mg/kg is used for active rheumatoid arthritis when conventional therapy has been ineffective. Side-effects include a rise in creatinine level and hypertension.

Physical measures

People with RA need constant advice and support from physiotherapists and nurse specialists, especially while they are learning to adjust. A combination of rest for active arthritis and exercises to maintain joint range and muscle power is essential. Exercise in a hydrotherapy pool is popular and effective. Advice about managing activities of daily living despite the arthritis, and about gadgets, seating or structural changes in the home or at work are helpful. Family and friends should be involved. Podiatry, shoe wear advice and psychological support should be offered to all people with RA.

Surgery

Surgery has a useful role in the long-term approach to patient management but is less frequently needed as therapeutic disease control becomes more effective. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Single-joint disease can be treated by surgical synovectomy to reduce the bulk of inflamed tissue and prevent damage. Excision arthroplasty of the ulnar styloid reduces pain and the risk of extensor tendon damage. Excision arthroplasties of the metatarsal heads reduce metatarsal pain and relieve pressure points. The major surgical advance has been the development of total replacement arthroplasty of the hip, knee, finger joints, elbow and shoulder. Such procedures need careful planning and preparation, and the expected outcomes and risks should be explained to the patient.

Prognosis

A poor prognosis is indicated by:

- **A clinical picture** of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved and the level of disability at the onset
- **Blood tests** showing a high CRP/ESR, normochromic normocytic anaemia and high titres of ACPA antibodies and of rheumatoid factor
- **X-rays** with early erosive damage (note: ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).

Prognosis can be altered dramatically with early DMARD therapy under expert supervision.

SPONDYLOARTHRITIS

This is a group of conditions affecting the spine and peripheral joints which cluster in families and are linked to certain type 1 HLA antigens (Table 11.17).

The joint involvement is usually more limited than that seen in RA and its distribution is different. There are associated extra-articular and genetic features. These diseases occasionally present in childhood.

Histologically, the synovitis itself is similar to that of RA, but there is no production of rheumatoid factors – hence ‘seronegative’. ACPA is also usually negative. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA. All are associated with an increased frequency of sacroiliitis and an increased frequency of HLA-B27.

Aetiology

The common aetiological thread of these disorders is their striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in >90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics including a high tendency to mis-fold but its aetiological relevance remains unclear. The role of class I HLA antigens in pathogenesis is supported by the fact that HLA-B27 transgenic mice spontaneously develop arthritis, skin, gut and genitourinary lesions.

There are clues that infections play a role, possibly by molecular mimicry, with parts of the organism which are structurally similar to the HLA molecule triggering cross-reactive antibody formation. This is unproven. AIDS is increasing the prevalence of reactive arthritis and spondylitis in sub-Saharan Africa even in the absence of HLA-B27. The explanation for this changing epidemiology is unclear.

The types of arthritis that follow a precipitating infection are called reactive arthritis (p. 529).

The specialized immune systems of the gut and genitourinary mucous membranes may also play a causal role,

perhaps reacting to local infections or to antigens which cross the damaged mucosa.

Ankylosing spondylitis (AS)

This is an inflammatory disorder of the spine affecting mainly young adults (late teens to early 30s). It occurs worldwide, with a male to female ratio of 5:1. Women present later and are underdiagnosed. The frequency of AS in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and ankylosing spondylitis, while the North American Haida Indians have a high incidence of both. There are at least 24 subtypes of HLA-B27 (B*2701-B*2724). Some appear to increase risk; others have a protective role. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic (up to 70%) twins than in dizygotic twins (about 20–25%). There are also other genes lying within the major histocompatibility complex (interleukin-1 gene cluster and the gene *CYP2D6*) which also influence susceptibility to AS but the disease is polygenic.

Epidemiology and pathogenesis

Environmental factors may also be involved but although Gram-negative organisms, e.g. *Yersinia*, *Klebsiella*, *Salmonella*, *Shigella*, can cause a reactive arthropathy, there is no conclusive evidence for their involvement in the pathogenesis of AS.

There is lymphocyte and plasma cell infiltration and local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis). This heals with new bone (syn-desmophyte) formation.

Clinical features

Episodic inflammation of the sacroiliac joints in the late teenage years or early 20s is the first manifestation of AS. Pain in one or both buttocks and low back pain and stiffness are typically worse in the morning and relieved by exercise. Initially the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent. Retention of the lumbar lordosis during spinal flexion is an early sign. Later, paraspinal muscle wasting develops.

Criteria for classifying inflammatory back pain as ankylosing spondylitis are shown in Box 11.14.

Spinal stiffness can be measured by Schober's test: a tape measure is placed in the midline 10 cm above the dimples of Venus. Any movement of a marker at 15 cm during flexion is recorded. A reading of <5 cm implies spinal stiffness. Individuals may be able to touch the floor with a stiff back if they have good hip movements but serial measurement of the finger tip to floor distance highlights any change.

Non-spinal complications (uveitis or costochondritis) suggest the diagnosis of spondyloarthritis (Box 11.15).

Costochondral junction inflammation causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.

Peripheral joint involvement is asymmetrical and affects a few, predominantly large joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of the posture. Young teenage boys occasionally present with a lower-limb monoarthritis (see p. 546), which later develops into AS.

Acute anterior uveitis is strongly associated with HLA-B27 in AS and related diseases and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see p. 1062).

Overall clinical assessment is based on pain, tenderness, stiffness and fatigue using, e.g. the Bath Ankylosing Spondylitis Disease Activity Index.

Investigations

- **Blood.** The ESR and CRP are usually raised.
- **HLA testing** is rarely of value because of the high frequency of HLA-B27 in the population, but may give supporting evidence in a difficult case.
- **X-rays.** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 11.20). The earliest radiological appearances in the spine are blurring of the

Box 11.15 Non-articular problems in spondyloarthritis

- Uveitis, in all types
- Cutaneous lesions in reactive arthritis (keratoderma blennorrhagica), histologically identical to pustular psoriasis
- Nail dystrophy, in psoriasis and reactive arthritis
- Aortitis, occasionally in AS and reactive arthritis

Box 11.14 Back pain criteria for diagnosing ankylosing spondylitis^a

- Age of onset <50 years
- Insidious onset
- Improvement of back pain with exercise
- No improvement of back pain with rest
- Pain at night with improvement on getting up

^aThe presence of four of the five criteria suggests AS with 80% sensitivity. ^aAll criteria have high sensitivity.

Figure 11.20 X-ray of ankylosing spondylitis. The sacroiliac joints are eroded and show marginal sclerosis (white arrows). There is bridging syndesmophyte formation at the thoracolumbar junction (black arrows).

Figure 11.21 X-ray of bamboo spine in ankylosing spondylitis. In advanced disease there is calcification of the interspinous ligaments and fusion of the facet joints as well as syndesmophytes at all levels. The sacroiliac joints fuse.

upper or lower vertebral rims at the thoracolumbar junction (best seen on a lateral X-ray) caused by an enthesitis at the insertion of the intervertebral ligaments. These changes may eventually affect the whole spine. Persistent inflammatory enthesitis causes bony spurs (syndesmophytes). Syndesmophytes are more vertically oriented than the beak-like osteophytes of spondylosis and the disc is preserved, unlike in spondylosis (see p. 503). Syndesmophytes cause bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a 'bamboo' spine (Fig. 11.21).

- **MRI** with gadolinium demonstrates sacroiliitis before it is seen on X-rays, and persistent enthesitis.

Treatment

- The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion.
- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles. This, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active and the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance. Peripheral arthritis and enthesitis are managed with NSAIDs or local steroid injections.
- Methotrexate is effective for peripheral arthritis but not for spinal disease.
- The TNF- α blocking drugs adalimumab and etanercept (Table 11.16) have revolutionized the lives of people with AS. They produce a rapid, dramatic and sustained reduction of symptoms and of spinal and peripheral joint inflammation. Around half the patients are able to stop NSAIDs. Relapse occurs on stopping therapy but may

Figure 11.22 Hand showing psoriatic arthritis mutilans. All the fingers are shortened and the joints unstable, owing to underlying osteolysis.

be delayed by several months making intermittent treatment feasible. Golimumab is also available for severe active disease unresponsive to conventional therapy. Rituximab does not help spondyloarthritis.

Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. Anti-TNF therapies are likely to reduce the morbidity of severe disease, reducing the risk of permanent spinal stiffness and progressive peripheral joint disease.

Patients should be made aware that they risk passing the HLA-B27 gene to 50% of their children. HLA-B27 positive offspring then have a 30% risk of developing AS.

Psoriatic arthritis

The prevalence of psoriasis is 2–3% worldwide, and in this population around 10% have arthritis (see p. 506). A family history of psoriasis may be a clue to the diagnosis. The aetiology and pathogenesis is described on page 509.

Clinical features

Patterns of psoriatic arthritis include:

- **Mono- or oligoarthritis**
- **Polyarthritis** virtually indistinguishable from RA
- **Ankylosing spondylitis**: uni- or bilateral sacroiliitis and early cervical spine involvement; only 50% are HLA-B27 positive
- **Distal interphalangeal arthritis**, which is the most typical pattern of joint involvement in psoriasis, often with adjacent nail dystrophy (see p. 1209) reflecting enthesitis extending into the nail root
- **Arthritis mutilans**, which affects about 5% of patients who have psoriatic arthritis and causes marked periarticular osteolysis and bone shortening ('telescopic' fingers) (Fig. 11.22).

Radiologically, **psoriatic arthritis** is erosive but the erosions are central in the joint, not juxta-articular, and produce a 'pencil in cup' appearance (Fig. 11.23). The skin and nail disease can be mild and may develop after the arthritis.

Treatment and prognosis

NSAIDs and/or analgesics help the pain but they can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections.

FURTHER READING

Braun J, Sieper J. Ankylosing spondylitis. *Lancet* 2007; 369: 1379–1390.

Figure 11.23 X-ray of psoriatic arthritis. There is osteolysis of the metatarsal heads and central erosion of the proximal phalanges to produce the 'pencil in cup' appearance (circle). All the lesser toes are subluxed.

In milder, polyarticular cases, sulfasalazine or methotrexate slows the development of joint damage.

When the disease is severe, methotrexate or ciclosporin is given because they control both the skin lesions and the arthritis. Anti-TNF- α agents, e.g. etanercept and golimumab (see p. 1210) and ustekinumab, are highly effective and safe for severe skin and joint disease. They should be given when methotrexate has failed. Corticosteroids orally may destabilize the skin disease and are best avoided but are valuable when injected into a single inflamed joint. Rituximab has no role in treating psoriatic arthritis.

The prognosis for the joint involvement is generally better than in RA.

Reactive arthritis

Reactive arthritis is a sterile synovitis, which occurs following an infection (see also post-streptococcal arthritis, p. 546).

Spondyloarthritis develops in 1–2% of patients after an acute attack of dysentery, or a sexually acquired infection – nonspecific urethritis (NSU) in the male, nonspecific cervicitis in the female. In male patients who are HLA-B27 positive, the relative risk is 30–50. Not all patients are HLA-B27 positive. Women are less commonly affected.

Aetiology

A variety of organisms can be the trigger, including some strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU, the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum*.

People with reactive arthritis are not more susceptible to infection but appear to respond differently. Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints, suggesting that this persistent antigenic material is driving the inflammatory process. The methods by which HLA-B27 increases susceptibility to reactive arthritis may include:

- T cell receptor repertoire selection
- Molecular mimicry causing autoimmunity against HLA-B27 and/or other self antigens

Figure 11.24 Clinical features of reactive arthritis.

- Mode of presentation of bacteria-derived peptides to T lymphocytes.

These are not mutually exclusive.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (p. 533), gonococcal arthritis (p. 546) and brucellosis (p. 533). In these, the borderline between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features (Fig. 11.24)

The arthritis is typically an acute, asymmetrical, lower-limb arthritis, occurring a few days to a couple of weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesitis (see p. 509). Seventy per cent recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis occurs in 30%. Acute anterior uveitis complicates more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- **Circinate balanitis** in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male the lesion is raised, red and scaly. Both heal without scarring.
- **Keratoderma blennorrhagica** – the skin of the feet and hands develops painless, red and often confluent raised plaques and pustules histologically similar to pustular psoriasis.
- **Nail dystrophy** occurs.

Treatment

Treating persisting infection with antibiotics alters the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners must be screened.

Pain responds well to NSAIDs and locally injected or oral corticosteroids. The majority of individuals with reactive arthritis have a single attack which settles, but a few develop

a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (Table 11.16). TNF- α blocking agents remain the drugs of next choice in severe and persistent disease but are rarely necessary.

Enteropathic arthritis associated with inflammatory bowel disease

Enteropathic synovitis occurs in up to 10–15% of patients who have ulcerative colitis and Crohn's disease (see p. 275). The link between the bowel disease and the inflammatory arthritis is not clear. Selective mucosal leakiness may expose the individual to antigens that trigger synovitis.

The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis also occurs. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis can persist even in well-controlled Crohn's disease.

Treatment

The inflammatory bowel disease should be treated (see p. 272). In all cases of enteropathic arthritis, the symptoms are helped by NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is more frequently prescribed than mesalazine as it may help both bowel and joint disease. The TNF- α blocking drug infliximab is used in inflammatory bowel disease (p. 272) and can help the arthritis.

CRYSTAL ARTHRITIS

Aetiology

Two main types of crystal account for the majority of crystal-induced arthritis. They are sodium urate and calcium pyrophosphate and are distinguished by their different shapes and refringence properties under polarized light with a red filter. Rarely, crystals of calcium apatite (see p. 515) or cholesterol cause acute synovitis.

Gout and hyperuricaemia

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular sodium urate crystals.

Epidemiology

The prevalence of gout is increasing mainly in developed countries, due to changing diets – purine rich foods, high saturated fats, fructose containing drinks and alcohol. The prevalence is 1.4% in the UK (increasing with age to 3% in women and 7% in men) and 2.7% in the USA. Asian populations are more at risk as their diet becomes more Western. Gout develops in men more than women (10:1) and rarely occurs before young adulthood (when it suggests a specific genetic defect), and seldom in premenopausal females. Some 85–90% of cases are idiopathic. The prevalence in older females is increasing with increased diuretic use. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine and of xanthine to uric acid, catalysed by the enzyme xanthine oxidase. Primates lost the gene for uricase during their evolution about 10–20 million years ago. Hyperuricaemia possibly offered an evolutionary advantage.

Figure 11.25 Serum uric acid levels in controls and in those with gout. 7.9 mg/dL is equivalent to 474 μ mol/L, 5.1 mg/dL is equivalent to 306 μ mol/L. (From Snaith ML, Scott JT. Uric acid clearance in patients with gout and normal subjects. *Annals of Rheumatic Disease* 1971; 30:285–289, with permission from the BMJ Publishing Group.)

Uric acid levels are higher in men than in women. There is a normal distribution of serum uric acid in the population with a skewed distribution at the upper end of the range. Hyperuricaemia is defined as a serum uric acid level greater than two standard deviations from the mean (420 μ mol/L in males; 360 μ mol/L in females). This is close to the limit of solubility – 360 μ mol/L at 35°C and 300 μ mol/L at 30°C.

Most people with hyperuricaemia are asymptomatic. Osteoarthritic joints are more prone to gouty attacks. The range for gouty individuals is higher than for normals, but the curves overlap (Fig. 11.25). Serum uric acid levels increase with age, obesity, a 'Western' diet (see above) and combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and hypertension (metabolic syndrome, p. 218). There is often a family history of gout.

Pathogenesis of hyperuricaemia and gout

Uric acid is the final product of endogenous and dietary purine metabolism in humans and levels in the blood depend on the balance between purine synthesis and the ingestion of dietary purines, and the elimination of urate by the kidney (66%) and intestine (33%).

Some 90% of people with gout have impaired excretion of uric acid (10% have increased production due to high cell turnover and <1% due to an inborn error of metabolism). Renal excretion is coordinated by a group of renal tubular urate transport molecules and a complex process of glomerular filtration, proximal tubule reabsorption via the urate transporter-1 (URAT-1) and active resecretion (Fig. 11.26). GLUT9 transports uric acid along with glucose and fructose into the cell from the tubule and back into the circulation. Both the entry of uric acid via the URAT-1 mechanism and the exit into circulation by GLUT9 can be blocked by uricosuric drugs such as probenecid. The body pool is about 1000 mg and 60% is turned over daily. Low-dose aspirin blocks uric acid secretion. Insulin resistance enhances uric acid resorption. Causes of hyperuricaemia are shown in Table 11.18.

Figure 11.26 Urate renal transport. The net result is that about 5–10% of the glomerular load is excreted in the urine under normal circumstances.

Table 11.18 Causes of hyperuricaemia

Impaired excretion of uric acid

Chronic renal disease (clinical gout unusual)
 Drug therapy, e.g. thiazide diuretics, low-dose aspirin
 Hypertension
 Lead toxicity
 Primary hyperparathyroidism or hypothyroidism
 Increased lactic acid production from alcohol, exercise, starvation
 Glucose-6-phosphatase deficiency (interferes with renal excretion)

Increased production of uric acid

Increased purine synthesis *de novo* due to:
 Hypoxanthine-guanine-phosphoribosyl transferase (HGPRT) reduction (an X-linked inborn error causing the Lesch-Nyhan syndrome)
 Phosphoribosyl-pyrophosphate synthase overactivity
 Glucose-6-phosphatase deficiency with glycogen storage disease type 1
 Increased turnover of purines due to:
 Myeloproliferative disorders, e.g. polycythaemia vera
 Lymphoproliferative disorders, e.g. leukaemia
 Others, e.g. carcinoma, severe psoriasis

Gout as an autoinflammatory disease

The roles of innate immunity and of the inflammasome suggest that crystal arthritis is an autoinflammatory disease, similar to the hereditary periodic fevers (p. 548). A series of receptors recognize bacteria and viruses as 'foreign' and eliminate them by activating the cytokine cascade. One such receptor (NLRP3) has recently been implicated in crystal-triggered inflammation. The activation of the inflammasome (p. 63) activates interleukin-1 β , which in turn activates more cells and triggers an IL-8 mediated influx of neutrophils. Ingestion by polymorphonuclear leucocytes of sodium urate crystals causes the release of pro-inflammatory cytokines, particularly interleukin-1 β and complement. Colchicine works by inhibition of microtubule formation necessary for this to occur. The involvement of IL-1 β indicates a potential role for the IL-1 β blocking agent anakinra in gout, in patients resistant to usual treatments.

Clinical features

Hyperuricaemia may be asymptomatic. It also causes:

- **Acute gout**, followed by an asymptomatic intercritical phase; a second acute attack likely within 2 years
- **Chronic interval gout**, with acute attacks superimposed on low grade inflammation and potential joint damage
- **Chronic polyarticular gout** is rare, except in elderly people on longstanding diuretic treatment, in renal

failure, or when allopurinol is started too soon after an acute attack

- **Tophaceous gout**
- **Urate renal stone** formation (p. 600).

Acute gout presents typically in a middle-aged male with sudden onset of agonizing pain, swelling and redness of the first MTP joint. The attack occurs at any time, but may be precipitated by too much food or alcohol, by dehydration or by starting a diuretic. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised serum urate suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken.

Chronic tophaceous gout (see below).

Investigations

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum uric acid** is usually raised (>600 $\mu\text{mol/L}$). If it is not, recheck it several weeks after the attack, as the level falls immediately after an acute attack. Acute gout rarely occurs with a serum uric acid in the lower half of the normal range below the saturation point of 360 $\mu\text{mol/L}$.
- **Serum urea, creatinine** and eGFR are monitored for signs of renal impairment.

Treatment

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. The first dose should be taken at the first indication of an attack:

- **Naproxen**: 750 mg immediately, then 500 mg every 8–12 hours
- **Diclofenac**: 75–100 mg immediately, then 50 mg every 6–8 hours
- **Indometacin**: 75 mg immediately, then 50 mg every 6–8 hours. For some, the frequency of side-effects is unacceptably high with indometacin.

After 24–48 hours, reduced doses are given for a further week. **Caution**: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- **Colchicine**: 1000 μg immediately, then 500 μg every 6–12 hours, but this causes diarrhoea or colicky abdominal pain
- **Corticosteroids**: oral prednisolone or intramuscular or intra-articular depot methylprednisolone.

Dietary advice

The first attacks may be separated by up to 2 years and are managed symptomatically. Individuals should be advised to reduce their alcohol intake, especially beer, which is high in purines and fructose. Non-diet carbonated soft drinks are also high in fructose. A diet which reduces total calorie and cholesterol intake and avoids such foods as offal, some fish and shellfish and spinach, all of which are rich sources of purines, is advised. This can reduce serum urate by 15% and

Crystal arthritis

a

b

Crystal arthritis. (a) Needle-shaped urate crystals. (b) A small intracellular pyrophosphate crystal. Both viewed under polarized light with a red filter.

delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the internet.

Treatment with agents that reduce serum uric acid levels

The aim of treatment is to reduce the uric acid level below the 360 $\mu\text{mol/L}$ level; some guidelines recommend below 300 $\mu\text{mol/L}$.

Allopurinol should only be used when the attacks are frequent and severe (despite dietary changes), associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. Allopurinol (300–600 mg) blocks the enzyme xanthine oxidase, which converts xanthine into uric acid (see Fig. 16.20). It reduces serum uric acid levels rapidly and is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. It should never be started within a month of an acute attack and always be started under cover of a course of NSAID or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout. The dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 $\mu\text{mol/L}$ level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious adverse event. This is rare, as is bone marrow suppression.

Febuxostat (80–120 mg) is a non-purine analogue inhibitor of xanthine oxidase but not other enzymes in the purine and pyrimidine pathway. It is well tolerated and as effective as allopurinol in trials and is safer in renal impairment as it is metabolized in the liver and not renally excreted. It has been approved by the FDA and is helpful in patients who cannot tolerate allopurinol but there are anxieties that it may increase cardiovascular risks. At time of writing, most doctors advise trying allopurinol first unless there are strong contraindications to its use.

Pegloticase, a pegylated recombinant uricase given intravenously, lowers urate levels dramatically but its place in therapy is unclear.

Uricosuric agents also lower the serum uric acid but their use is restricted throughout Europe by the very rare occurrence of serious hepatotoxicity. *Benzbromarone* acts on the URAT-1 transporter and is well tolerated. *Sulphinpyrazone* and *probenecid* are best avoided in renal impairment. Availability of these drugs varies between countries – in the UK benzbromarone and probenecid can be obtained for treating named patients.

Losartan is an angiotensin I-receptor antagonist and is uricosuric in hypertensive patients with gout. It may reduce the risk of gout in patients with the metabolic syndrome.

Anakinra blocks IL-1 β and **canakinumab** is a human monoclonal antibody with specific cross-reactivity for IL-1 β but not other members of the IL-1 family. Their role in treatment-resistant gout is still subject to trials to establish when their use is justified in gout which has not responded to the more conventional agents.

Chronic tophaceous gout

Individuals with very high levels of uric acid can present with chronic tophaceous gout, as sodium urate forms smooth white deposits (tophi) in skin and around joints. They occur on the ear, the fingers (Fig. 11.27) or the Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined ('punched-out') bone cysts on X-ray.

Figure 11.27 Gout with tophi. (Courtesy of Dr Varkey Alexander, Al-Sabah Hospital, Kuwait.)

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, stop the diuretics or change to less urate-retaining ones, such as bumetanide. Treat with allopurinol and/or uricosuric agents (see above). Pegylated uricase (Pegloticase), a pegylated recombinant uricase given intravenously, is used preventatively in people undergoing chemotherapy for malignancies (tumour lysis syndrome). Pegloticase has an important but, as yet, unproven role in those rare individuals who have refractory tophaceous gout.

Pseudogout (pyrophosphate arthropathy)

Calcium pyrophosphate deposits in hyaline and fibrocartilage produce the radiological appearance of chondrocalcinosis (see p. 515). Shedding of crystals into a joint precipitates acute synovitis which resembles gout, except that it is more common in elderly women and usually affects the knee or wrist. The attacks are often very painful. In young people it may be associated with haemochromatosis, hyperparathyroidism, Wilson's disease or alkaptonuria.

Diagnosis

The diagnosis is made by detecting rhomboidal, weakly positively birefringent crystals in joint fluid, or deduced from the presence of chondrocalcinosis on X-ray. The joint fluid looks purulent. Septic arthritis must be excluded and joint fluid should be sent for culture. The attacks may be associated with fever and a raised white blood cell count.

Treatment

Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an intra-articular injection of a corticosteroid helps.

INFECTIONS OF JOINTS AND BONES

Joints become infected by direct injury or by blood-borne infection from an infected skin lesion or other site.

Chronically inflamed joints (e.g. in rheumatoid arthritis) are more prone to infection than are normal joints. Individuals who are immunosuppressed, by AIDS or by immunosuppressive agents, are particularly at risk, as are infants, the elderly and those who use excess alcohol. Artificial joints are also potential sites for infection.

Septic arthritis

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae*, *Haemophilus influenzae* in children, and these

FURTHER READING

Burns CM, Wortmann RL. Gout therapeutics: new drugs for old disease. *Lancet* 2011; 377:165–177.

and other Gram-negative organisms in the elderly or complicating RA.

Clinical features

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen and agonizingly painful and held immobile by muscle spasm. In the elderly and immunosuppressed and in RA the clinical picture is less dramatic, so a high index of suspicion is needed to avoid missing treatable but potentially severely destructive and occasionally fatal septic arthritis.

In 20% of patients, the sepsis affects more than one joint. Chronic destructive arthritis due to tuberculosis is rare.

Investigations

- **Aspirate** the joint and send the fluid for urgent Gram-staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- **X-rays** are of no value in diagnosis in acute septic arthritis.
- **Skin wound swabs, sputum and throat swab or urine** may be positive and indicate the source of infection.

Treatment

This should be started immediately on diagnosis because joint destruction may occur within weeks. The joint should be immobilized initially and then physiotherapy started early to prevent stiffness and muscle wasting. Intravenous antibiotics should be given for 1–2 weeks. It is usual to give two antibiotics to which the organism is sensitive for 6 weeks, then one for a further 6 weeks, orally. Monitor clinically and with the ESR and CRP.

Empirical treatment in septic arthritis

This is started before the results of culture are obtained. Discuss the case with a microbiologist. Intravenous flucloxacillin 1–2 g is given 6-hourly, plus fusidic acid 500 mg orally 8-hourly. If the patient is allergic to penicillin, replace flucloxacillin with erythromycin 1 g i.v. 6-hourly or clindamycin 600 mg i.v. 8-hourly. In immunosuppressed patients, flucloxacillin 1–2 g i.v. 6-hourly plus gentamicin (to cover Gram-negative organisms) should be used. Teicoplanin i.v. should replace flucloxacillin if MRSA is likely. Change the antibiotics if the organism is not sensitive. Drainage of the joint and arthroscopic joint washouts are helpful in relieving pain.

Management of infected prostheses

If chronically infected, the prosthesis is removed and the joint space filled with an antibiotic-impregnated spacer for 3–6 weeks before a new prosthesis is inserted. The whole process is covered by antibiotics, e.g. teicoplanin i.v. and oral sodium fusidate.

Specific types of bacterial arthritis

Gonococcal arthritis

This is the most common cause of a septic arthritis in previously fit young adults; more commonly affecting women and men who have sex with men.

Initially the patient becomes febrile and develops characteristic pustules on the distal limbs. Polyarthralgia and tenosynovitis are common at this stage and about 40% have a gonococcaemia. This phase settles and blood cultures

usually become negative. Nucleic acid amplification tests are a useful adjunct to cultures and may be positive even when cultures are negative. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this is simply a septic arthritis – although it responds rapidly to antibiotics, or whether there is also a reactive element to bacterial lipopolysaccharide.

Treatment consists of oral penicillin, ciprofloxacin or doxycycline for 2 weeks, and joint rest. Resistance to antibiotics is increasing.

Tuberculous arthritis

Around 1% of people with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet's disease).

The hip or knee (30%) is quite commonly affected, but around 50% develop spinal disease. The patient is febrile, has night sweats, is anorexic and loses weight. The usual risk factors for tuberculosis apply – debility, excess alcohol use or immunosuppression. HIV-positive/AIDS patients are at particular risk.

Investigations should include culture of fluid, and culture and biopsy of the synovium. *M. tuberculosis* is the usual organism, but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is often necessary to obtain cultures.

Treatment is as for pulmonary tuberculosis with therapy for 9 months (see p. 820). The joint should be rested and the spine immobilized in the acute phase.

Meningococcal arthritis

This may complicate a meningococcal septicaemia and presents as a migratory polyarthritis. Organisms can only rarely be cultured from the joint and most cases are due to immune complex deposition. Treatment is urgent with immediate penicillin therapy (p. 75).

Infective endocarditis

This may present with arthralgia, polymyalgia rheumatica-like symptoms or an infective arthritis. It is discussed on page 687.

Lyme arthritis

About 25% of people with Lyme disease develop arthralgia, less commonly an acute pauciarticular arthritis (see p. 130). This usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers in these patients of an ongoing infection (p. 130).

Diagnosis is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

Treatment with antibiotics (amoxicillin or doxycycline) is highly effective in early disease. The response of chronic arthritis to antibiotic treatment is discussed on page 130.

Brucellosis

Brucellosis (see p. 129) has a worldwide distribution. The most common cause of chronic brucellosis and of arthritis is

FURTHER READING

Mathews CJ, Weston VC, Jones A et al. Bacterial septic arthritis in adults. *Lancet* 2010; 375:846–855.

Brucella melitensis. There is usually a migratory large joint mono- or oligoarticular arthritis, which is septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

Syphilitic arthritis

Congenital syphilis (see p. 166) can cause an acute painful epiphysitis or osteochondritis sometimes associated with para-articular swelling in the first few weeks of life. Later, at age 8–16 years, painless effusion of the knees may occur (Clutton's joints).

In acquired syphilis, arthralgia and arthritis occur in the secondary stage. Charcot's (neuropathic) joints usually involve the knees in tabes dorsalis (see p. 1129).

Leprosy (p. 130)

Acute or chronic symmetrical polyarthritis resembling RA, swollen hands and feet due to lepra reactions, tenosynovitis and thickened nerves with or without cutaneous manifestations are seen in leprosy.

Actinomycetes infection

Actinomycetes can affect the mandible or vertebrae.

Arthritis in viral disease

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythrovirus B19, hepatitis B and C, arboviral infections and HIV. In most of these it is due to a direct toxic effect or immune complex deposition.

In **rubella** (see p. 104) the virus can occasionally be isolated from the joint. This arthritis is rare in countries where rubella vaccination is routine. It occurs most commonly in up to 50% of young adult females a few days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles rheumatoid arthritis. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

Erythrovirus B19 (p. 101) causes an acute, self-limiting arthritis and is associated with erythema infectiosum ('slapped cheek disease').

In **hepatitis B** infection (see p. 318), a sudden symmetrical polyarticular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase and mostly resolving before the onset of jaundice. Hepatitis C infection causes type II mixed cryoglobulinaemia (see p. 323).

Arbovirus infections (see p. 104) which are endemic in many parts of the world, give rise to an arthralgia and/or arthritis. For example, the Ross River virus causes an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya (p. 105) and O'nyong-nyong.

Musculoskeletal aspects of infection with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS)

The clinical features seen in these patients are due to a number of causes such as opportunistic infections and drug therapy and are not usually caused directly by HIV. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Some of the antiviral agents

cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a *seronegative, predominantly lower-limb arthritis*, similar to psoriasis or Reiter's disease. *Spondylitis* also occurs but is not HLA-B27 associated. *Avascular necrosis*, possibly associated with corticosteroids or alcohol, is seen.

Non-articular diseases such as Sjögren- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types and myositis also occur.

Fungal infection

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

Bone infections**Acute and chronic osteomyelitis**

Osteomyelitis can be due either to metastatic haematogenous spread (e.g. from a boil) or to local infection. Malnutrition, debilitating disease and decreased immunity may play a part in the pathogenesis.

Staphylococcus is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and *Salmonella*; infection with the latter may occur as a complication of sickle cell anaemia. The classic presentation is with fever and localized bone pain with overlying tenderness and erythema.

Diagnosis

- **Imaging:**
 - Plain X-ray is not sensitive in early infection but osteopenia may be present.
 - MRI is highly sensitive, showing marrow oedema in 3 days.
 - Bone scans are also helpful.
- **Blood cultures** are often positive with staphylococcal infection.
- **Bone biopsy and culture** identifies the organism and sensitivities.

Treatment

Treatment of osteomyelitis is with immobilization and antibiotic therapy with intravenous teicoplanin or intravenous flucloxacillin 1–2 g every 6 hours and oral fusidic acid. Switch to oral antibiotics after 2 weeks and continue for a further 4 weeks. Surgical drainage and removal of dead bone (sequestrum) may be necessary but recurrence is common.

Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis sinus formation is usual. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie's abscess). Symptoms may be limited to local pain.

Tuberculous osteomyelitis

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (Pott's disease), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later an abscess forms ('cold abscess'). Pus can track along tissue planes and discharge at a point far from the affected vertebrae.

Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

Treatment is as for pulmonary tuberculosis but extended to 9 months (see p. 811), together with initial immobilization.

AUTOIMMUNE RHEUMATIC DISEASES

Autoimmunity and autoantibodies

Autoimmune diseases are conditions in which the immune system attacks tissues of the body. The antigens can be present in multiple organs so the clinical manifestations are systemic and diverse. In some diseases, such as Graves' disease, Hashimoto's thyroiditis, and insulin-dependent diabetes mellitus only a single organ is affected. The term 'autoimmune rheumatic disease' (ARD) is preferable to the older term 'connective tissue disease' because the clinical effects of ARD are not limited to connective tissues. Each individual ARD has a characteristic pattern of symptoms and signs, which are used to make the diagnosis. In some ARD there are also characteristic autoantibodies (i.e. antibodies that recognize antigens which are normal constituents of the body, such as DNA and phospholipids). Positive blood tests for autoantibodies are useful but not essential in the diagnosis of ARD (Table 11.3, p. 497).

Systemic lupus erythematosus (SLE)

SLE is an inflammatory, multisystem autoimmune disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

Epidemiology

SLE occurs worldwide and is about nine times as common in women as in men, with a peak age of onset between 20 and 40 years. The prevalence varies between ethnic groups, being highest (at 1:250) in African/Caribbean women. In other populations, the prevalence varies between 1:1000 and 1:10000.

Aetiology

The cause is unknown but there are several predisposing factors.

- **Heredity.** There is a higher concordance rate in monozygotic twins (up to 25%) compared with dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease, but approximately 20% have autoantibodies.
- **Genetics.** Recent research, including three whole genome analyses, has led to the identification of approximately 20 genes linked to the development of SLE. These include some HLA genes as well as genes involved in T and B lymphocyte function. Homozygous deficiencies of the complement genes C1q, C2 or C4 are very rare but convey a high risk of developing SLE.
- **Sex hormone status.** Premenopausal women are most frequently affected.
- **Drugs** such as hydralazine, isoniazid, procainamide and penicillamine can induce a form of SLE which is usually mild in that kidneys and the CNS are not affected.
- **Ultraviolet light** can trigger flares of SLE, especially in the skin.

- **Exposure to Epstein-Barr virus** has been suggested as a trigger for SLE.

Pathogenesis

When cells die by apoptosis, the cellular remnants appear on the cell surface as small blebs which carry self-antigens. These antigens include nuclear constituents (e.g. DNA and histones), which are normally hidden from the immune system. In people with SLE, removal of these blebs by phagocytes is inefficient so that they are transferred to lymphoid tissues where they can be taken up by antigen-presenting cells. The self-antigens from these blebs can then be presented to T cells which in turn stimulate B cells to produce autoantibodies directed against these antigens (p. 69). It has been shown that in some patients the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self-antigens and failure of the immune system to inactivate B cells and T cells which recognize these self-antigens (i.e. a breakdown of *tolerance*, see Ch. 3, p. 69) leads to the following immunological consequences.

- Development of autoantibodies that either form circulating complexes or deposit by binding directly to tissues
- This leads to activation of complement and influx of neutrophils causing inflammation in those tissues
- Abnormal cytokine production: increased blood levels of IL-10 and alpha-interferon are particularly closely linked to high activity of inflammation in SLE.

Pathology

SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies and influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles and venules. The synovium of joints can be oedematous and may contain immune complexes. Haematoxylin bodies (rounded blue homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

Clinical features

The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia and/or skin problems. Involvement of major organs is less common but more serious (Fig. 11.28).

General features

Fever is common in exacerbations. Patients complain of marked malaise and tiredness and these symptoms do not correlate with disease activity or severity of organ-based complications.

The joints and muscles

Joint involvement is the most common clinical feature (>90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint

Figure 11.28 Clinical features of systemic lupus erythematosus (SLE).

deformity resembling RA (known as Jaccoud's arthropathy) is seen. Avascular necrosis affecting the hip or knee is a rare complication of the disease or of treatment with corticosteroids.

Myalgia is present in up to 50% of patients but a true myositis is seen only in <5%. If myositis is prominent, the patient may well have an overlap ARD with both polymyositis and SLE.

The skin

The skin (see p. 1219) is affected in 85% of cases. Erythema, in a 'butterfly' distribution on the cheeks of the face and across the bridge of the nose (see Fig. 24.26), is characteristic. Vasculitic lesions on the finger tips and around the nail folds, purpura and urticaria occur. In 40–50% of cases there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia are seen. Scarring alopecia can lead to irreversible bald patches which are especially upsetting for women, who form the majority of people with SLE. Raynaud's phenomenon (see p. 788) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see p. 1198). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 1198.

The lungs

Up to 50% of patients will have lung involvement sometime during the course of the disease (see p. 848). Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis

and atelectasis are seen; eventually a restrictive lung defect develops with loss of lung volumes and raised hemidiaphragms. This 'shrinking lung syndrome' is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes. Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

The heart and cardiovascular system

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud's, vasculitis, arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in people with SLE. This is partly due to altered levels of common risk factors such as hypertension and lipid levels but the presence of chronic inflammation over many years may also play a role. It is not known whether intensive treatment of cardiovascular risk factors in SLE will alter the risk of developing coronary disease or stroke. The benefit of statin therapy in the absence of significant hypercholesterolaemia remains to be proved.

The kidneys

A classification of types of nephritis is on page 574. Autopsy studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal vein thrombosis can occur in nephrotic syndrome or associated with antiphospholipid antibodies.

The nervous system

Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression but occasionally more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polyneuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune-complex deposition, thrombosis or non-inflammatory microvasculopathy. The commonest finding on MRI scan is of increased white matter signal abnormality. In people with cerebral lupus, infection should be excluded or treated in parallel with administration of corticosteroids and immunosuppression.

The eyes

Retinal vasculitis can cause infarcts (cytoid bodies) which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjögren's syndrome is seen in about 15% of cases.

The gastrointestinal system

Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected

and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.

Investigations

■ Blood:

- A full blood count may show a leucopenia, lymphopenia and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis, arthritis or a co-existent infection.
- Urea and creatinine only rise when renal disease is advanced. Low serum albumin or high urine albumin/creatinine ratio are earlier indicators of lupus nephritis.
- Autoantibodies: many different autoantibodies may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm and anti-La (see Box 11.16). Antiphospholipid antibodies are present in 25–40% of cases but not all of these patients develop antiphospholipid syndrome (see below).
- Serum complement C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves but in some patients anti-dsDNA levels remain high even during clinical remission.

- **Histology.** Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.

- **Diagnostic imaging.** CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MR can detect lesions in white matter which are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Management

General measures

The disease and its management should be discussed with the patient, particularly the effect upon the patient's lifestyle, e.g. appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors (p. 727).

Symptomatic treatment

Many patients do not need treatment with corticosteroid tablets or immunosuppressive agents. Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs (p. 511). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs but patients require regular eye checks because of rare retinal toxicity (1 in 2000).

Corticosteroids and immunosuppressive drugs

Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal (p. 578) or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but is being replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Newer agents, which specifically target cells or cytokines in the immune system, are coming into use, especially in refractory cases. These include rituximab (anti-CD20) and belimumab, which are both monoclonal antibodies acting against B lymphocytes.

Course and prognosis

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints as seen in RA and OA occurs rarely, but a few patients develop deformities such as ulnar deviation. People with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

Pregnancy and SLE

Fertility is usually normal except in severe disease and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in women with antiphospholipid antibodies. Exacerbations can occur during pregnancy with frequent exacerbations of the disease post-partum. The patient's medications should be reviewed. Mycophenolate should be stopped whereas azathioprine,

Box 11.16 Antinuclear autoantibodies and disease associations

Antibody	Disease	Prevalence
ds DNA	SLE	70%
Anti-histone	Drug-induced lupus	–
Anti-centromeric	Limited SS	70%
Anti-Ro (SS-A)	SLE	40–60%
	Primary Sjögren	60–90%
Anti-La (SS-B)	SLE	15%
	Primary Sjögren	35–85%
Anti-Sm	SLE	10–25% (Caucasian) 30–50% (Black African)
Anti-UI-RNP	SLE Overlap syndrome	30%
Anti-Jo-1 (antisynthetase)	Polymyositis Dermatomyositis	30%
Anti-topoisomerase-1 (Scl-70)	Diffuse cutaneous SSc	30%

SS-A, SS-B, Sjögren's syndrome -A and -B; -Ro, -La, first two letters of name of patients; Sm, Smith, patient's name; RNP, ribonucleoprotein; SSc, systemic sclerosis.

hydroxychloroquine and low-dose oral corticosteroids are safe. Hypertension must be controlled. People with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis and fetal heart block).

Antiphospholipid syndrome

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages and who also have persistently positive blood tests for antiphospholipid antibodies (aPL) have the antiphospholipid syndrome (APS). aPL can be detected by several different tests:

- The **anticardiolipin test**, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin
- The **lupus anticoagulant test**, which detects changes in the ability of blood to clot in a test tube. Despite the name, this is not a test for lupus. It is a test for APS. The *anticoagulant* effect caused by aPL in the test tube causes an opposite *procoagulant* effect inside the body, because the balance of factors stimulating thrombosis is different there.
- The **anti- β_2 -glycoprotein I test**, which detects antibodies that bind β_2 -glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e. positive on at least two occasions, ≥ 12 weeks apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never get APS, i.e. not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

Pathogenesis

Negatively charged phospholipids and β_2 -glycoprotein I are present on the outer surface of apoptotic blebs and so aPLs are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPLs bind to the N-terminal domain of β_2 -glycoprotein I and this interaction is facilitated when the protein is bound to phospholipid on the surface of cells such as endothelial cells, platelets, monocytes and trophoblasts. This alters the functioning of those cells leading to thrombosis and/or miscarriage.

Clinical features

Since APS is defined by the presence of thrombosis and/or pregnancy loss it is not surprising that these are the most common features. Ischaemic strokes occur in about 20% of patients and deep vein thrombosis in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Of women who have had two or more spontaneous miscarriages, 27% have APS.

However, large studies show that people with APS can also have many other features including:

- Thrombocytopenia
- Chorea, migraine and epilepsy
- Valvular heart disease
- Cutaneous manifestations (e.g. livedo reticularis)
- Positive Coombs test
- Renal impairment due to ischaemia in the small renal vessels.

Occasionally, APS is catastrophic. Catastrophic APS is a rare variant (about 1% of cases) in which multiple infarcts in different organs of the body cause failure of multiple organs simultaneously. There is a high mortality from catastrophic APS.

Treatment

In people with APS who have had one or more thrombosis, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin. The optimal target INR is unclear and many patients are managed with lower target INR. Pregnant women with APS are given oral aspirin and subcutaneous heparin from early in gestation. This reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. There are no definite guidelines for managing people with aPL who have never had thrombosis. Aspirin or clopidogrel are sometimes given prophylactically, especially in those with high IgG aPL. Warfarin is given much more rarely in these circumstances.

Systemic sclerosis (scleroderma)

Systemic sclerosis (SSc) (see p. 1218), is a multisystem disease. This distinguishes it from localized scleroderma syndromes, such as morphea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud's phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. SSc occurs worldwide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include: exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichloroethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Vascular features

An early lesion is widespread vascular damage involving small arteries, arterioles and capillaries. There is initial endothelial cell damage with release of cytokines including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation, activation of adhesion molecules (E-selectin, VCAM, ICAM-1), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5. All these factors cause release of other mediators (e.g. interleukin-1, -4, -6 and -8, transforming growth factor- β and platelet-derived growth factor) with activation of fibroblasts.

The damage to small blood vessels also produces widespread obliterative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet-derived growth factor receptor, which have been found in

Figure 11.29 Clinical features of systemic sclerosis.

blood of people with SSc, stimulate fibroblasts to cause fibrosis.

Clinical features (Fig. 11.29)

Raynaud's phenomenon

Raynaud's phenomenon is seen in almost 100% of cases and can precede the onset of the full-blown disease by many years.

Limited cutaneous scleroderma (LcSSc): 70% of cases

This usually starts with Raynaud's phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic 'beak'-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common. Pulmonary hypertension (PHT) develops in 21% of people with LcSSc and pulmonary interstitial disease also occurs.

Diffuse cutaneous scleroderma (DcSSc): 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud's phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening, which can involve most of the body in the severest cases. Later the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- Heartburn, reflux or dysphagia due to oesophageal involvement is almost invariable and anal incontinence occurs in many patients. Malabsorption from bacterial

overgrowth due to dilatation and atony of the small bowel is not infrequent, and more rarely dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.

- Renal involvement is acute or chronic. Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. ACE inhibitors and better care along with dialysis and renal transplantation have changed this.
- Lung disease, both fibrosis (in 41% of cases) and pulmonary hypertension (17% of cases), contributes significantly to mortality in SSc. PHT can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- Myocardial fibrosis leads to arrhythmias and conduction defects. Pericarditis is found occasionally.

Sometimes, these systemic features occur without skin involvement (SSc sine scleroderma).

Investigations

- **Full blood count.** A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia is seen in some people with renal disease.
- **Urea and electrolytes.** Urea and creatinine rise in acute kidney injury.
- **Autoantibodies (Box 11.16):**
 - a. In LcSSc: speckled, nucleolar or anti-centromere antibodies (ACAs) occur in 70% of cases.
 - b. In DcSSc: there are anti-topoisomerase-1 antibodies (called anti-Scl-70) in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20–25%. Anti-Scl-70 is highly specific for DcSSc. Anti-RNA polymerase positivity is associated with pulmonary fibrosis.
 - c. *Rheumatoid factor* is positive in 30%.
 - d. ANA is positive in 95%.
- **Urine** microscopy and, if there is proteinuria, urine albumin/creatinine ratio should be measured.
- **Imaging:**
 - a. CXR: to exclude other pathology, for changes in cardiac size and established lung disease
 - b. Hands: deposits of calcium around fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges, termed 'acroosteolysis')
 - c. Barium swallow generally confirms impaired oesophageal motility. Scintigraphy, manometry, impedance, and upper GI endoscopy are also valuable
 - d. High-resolution CT: to demonstrate fibrotic lung involvement.
- **Other investigations** of gastrointestinal tract (e.g. see Fig. 6.5), lung, renal and cardiac as appropriate.

Management

Treatment should be organ-based in order to try to control the disease. Currently, there is no cure. In contrast to many other ARDs, corticosteroids and immunosuppressants are rarely used in SSc, with the exception of SSc-related pulmonary fibrosis.

- Education, counselling and family support are essential.

- Regular exercises and skin lubricants may limit contractures but no treatment has proven efficacy in reducing skin fibrosis.
- Raynaud's may be improved by hand warmers and oral vasodilators (calcium-channel blockers, ACE inhibitors, angiotensin receptor blockers). In severe cases, parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide) are used. Lumbar sympathectomy can help foot symptoms. Radical micro-arteriolysis (digital sympathectomy) can be used where individual fingers or toes are severely ischaemic and thoracic sympathectomy under video assisted thoracic surgery is now performed.
- Oesophageal symptoms can almost always be improved by proton pump inhibitors, but prokinetic drugs are rarely helpful.
- Symptomatic malabsorption requires nutritional supplements and rotational antibiotics to treat small intestinal bacterial overgrowth.
- Renal involvement requires intensive control of hypertension. First drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage dcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.
- Pulmonary hypertension is treated with oral vasodilators, oxygen and warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous or intravenous) or the oral endothelin-receptor antagonists (bosentan and sitaxsentan). Right heart failure is treated conventionally and transplantation (heart-lung or single lung) is used in eligible cases.
- Pulmonary fibrosis is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.

Prognosis

In limited cutaneous scleroderma the disease is often milder, with much less severe internal organ involvement and a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphea, p. 1218) or linear forms. These are more commonly seen in children and adolescents and do not convert into systemic forms, although ANA may occur in localized scleroderma and very occasionally there is co-existence of localized and systemic forms.

Polymyositis (PM) and dermatomyositis (DM)

Polymyositis is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved it is called 'dermatomyositis'. The incidence is about 2–10/million population per annum and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g. *Coxsackie*, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

Clinical features

Adult polymyositis

Women are affected three times more commonly than men.

The onset can be insidious, over months, or acute. General malaise, weight loss and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

Adult dermatomyositis

This is also more common in women. Apart from muscle weakness these patients often suffer from myalgia, polyarthritides and Raynaud's phenomenon but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers where one sees purple-red raised vasculitic patches. These patches occur over the knuckles (Gottron's papules) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue occurs in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.

Other organ involvement (antisyntetase syndrome)

Some 20–30% of people with PM or DM have antibodies to tRNA synthetase enzymes. These people are more likely to develop pulmonary interstitial fibrosis, Raynaud's phenomenon, arthritis and hardening and fissuring of skin over the pulp surface of the fingers (mechanic's hands). This variant of PM/DM is sometimes called antisyntetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

Association with other ARD

There is an association with other ARD (e.g. SLE, RA and SSC) with their associated clinical features such as deforming arthritis, malar rash and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture does not differ from that of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent, refractory or ANA-negative DM should prompt a search for occult malignancy.

Malignancy (e.g. lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

Childhood dermatomyositis

This most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature.

Investigations

- **Serum creatine kinase (CK)**, aminotransferases, lactate dehydrogenase (LDH) and aldolase are usually raised

and are useful guides to muscle damage but may not reflect activity.

- **ESR and CRP** may be raised.
- **Serum autoantibody studies.** Antinuclear antibody testing is usually positive in people with DM. Rheumatoid factor is present in up to 50% and many *myositis-specific* antibodies (MSAs) have been recognized and correlate with certain subsets. Antisynthetase antibodies have been described above.
- **Electromyography (EMG)** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest; polyphasic or short-duration potentials on voluntary contraction; and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormally inflamed muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively noninvasive investigations such as CXR, mammography, pelvic/abdominal ultrasound, urine microscopy and a search for circulating tumour markers.
- **PET** scan for malignancy.

Treatment

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment; 0.5–1.0 mg/kg body weight as initial therapy continued until at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate mofetil is common, especially where there is clinical relapse or rise in CK as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive with earlier use of immunosuppressive agents. Use of biological agents such as rituximab has been described but they are not commonly used.

INCLUSION BODY MYOSITIS

Inclusion body myositis is an idiopathic inflammatory myopathy occurring usually in men over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the creatine kinase is only slightly elevated; the EMG shows both myopathic and neuropathic changes. On MRI, the changes are often more distal but can be similar to polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

Sjögren's syndrome

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of rheumatoid arthritis or any of the autoimmune diseases is known as 'primary Sjögren's syndrome'. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary

and parotid gland enlargement is seen. In the majority of cases dryness and fatigue are the only symptoms, and Sjögren's syndrome is irritating and inconvenient rather than dangerous. However, in a minority there may be systemic symptoms such as:

- Arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud's phenomenon
- Dysphagia and abnormal oesophageal motility as seen in systemic sclerosis (but less common)
- Other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis, autoimmune hepatitis and pancreatitis
- Renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis
- Pulmonary diffusion defects and fibrosis
- Polyneuropathy, fits and depression
- Vasculitis
- Increased incidence of non-Hodgkin's B cell lymphoma.

Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test.** A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of <10 mm in 5 min indicates defective tear production.
- **Rose Bengal staining** of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities.** These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. Rheumatoid factor is usually positive. Antinuclear antibodies are found in 80% of cases and anti-mitochondrial antibodies in 10%. Anti-Ro (SSA) antibodies are found in 60–90%, compared with 10% of cases of RA and secondary Sjögren's syndrome. This antibody is of particular interest because it can cross the placenta and cause congenital heart block.

Purplish Gottron's papules over the knuckles (dermatomyositis). (Courtesy of David Paige, London.)

Management

Symptomatic treatment is with artificial tears and saliva-replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy.

'Overlap' syndromes and undifferentiated autoimmune rheumatic disease

An **overlap syndrome** is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as if they occurred separately.

Undifferentiated ARD is a term used for patients who have evidence of autoimmunity (e.g. positive autoantibody test) and some clinical features of such diseases (commonly Raynaud's phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.

SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (Tables 11.19, 11.20). The group of diseases described in this section (systemic inflammatory vasculitides) is characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. Two main features are helpful in classifying these vasculitides; the size of the blood vessels involved and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA) in the blood (Fig. 11.30 and Table 11.19).

- **Large vessel vasculitis** refers to the aorta and its major tributaries.

- **Medium vessel vasculitis** refers to medium and small-sized arteries and arterioles.
- **Small vessel vasculitis** refers to small arteries, arterioles, venules and capillaries.

Large vessel vasculitis

Polymyalgia rheumatica (PMR) and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis on temporal artery biopsy.

Polymyalgia rheumatica (PMR)

PMR causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine; a limb girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The

Table 11.19 Types of systemic vasculitis

Large	Giant cell arteritis/ polymyalgia rheumatica

Figure 11.30 Clinical features of systemic inflammatory vasculitides. These illnesses all frequently present with joint pain as well as systemic symptoms such as fatigue, malaise and weight loss. The commonest organ-specific manifestations are shown. Giant cell arteritis is usually seen in people over 50, whereas Takayasu's disease is seen in people under 50. Kawasaki's disease is usually seen in children under 5.

Box 11.17 Symptom patterns in some muscle disorders

- **Polymyositis** – proximal muscle ache and weakness
- **Polymyalgia rheumatica** – proximal morning stiffness and pain
- **Myopathy** – weakness, but no pain or stiffness

clinical history is usually diagnostic and the patient is always over 50 years old.

Approximately one-third of patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats especially if PMR is not diagnosed and treated early. A differential diagnosis is shown in Box 11.17.

Investigation of PMR

- **A raised ESR and/or CRP** is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- Serum alkaline phosphatase and γ -glutamyl-transpeptidase may be raised as markers of the acute inflammation.
- **Anaemia** (mild normochromic, normocytic) is often present.
- **Temporal artery biopsy** shows giant cell arteritis in 10–30% of cases, but is rarely performed unless GCA is also suspected.

Giant cell arteritis (GCA)

GCA is inflammatory granulomatous arteritis of large cerebral arteries which occurs in association with PMR. The patient may have current PMR, a history of recent PMR, or be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness and swelling of one or more temporal or occipital arteries. The most feared manifestation is sudden painless temporary or permanent loss of vision in one eye due to involvement of the ophthalmic artery (see p. 1105). Systemic manifestations of severe malaise, tiredness and fever occur.

Investigation of GCA

- **Normochromic, normocytic anaemia**
 - **ESR** is usually raised (in the region of 50–120 mm/h) and the CRP very high
 - **Liver biochemistry.** Abnormalities occur, as in PMR. The albumin may be low
 - **A temporal artery biopsy** from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (>1 cm long) must be examined; even so, negative biopsies occur.
- The histological features of GCA are:
- Cellular infiltrates of CD4+ T lymphocytes, macrophages and giant cells in the vessel wall. Note that giant cells are not visible in all cases
 - Granulomatous inflammation of the intima and media

- Breaking up of the internal elastic lamina
- Giant cells, lymphocytes and plasma cells in the internal elastic lamina.

Treatment of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned and an alternative cause sought, such as RA, vasculitis, infection or malignancy. This treatment should reduce the risk of patients who have PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange a temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting daily doses of prednisolone are:

- **PMR:** 10–15 mg prednisolone as a single dose in the morning
- **GCA:** 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg the reduction can be in 2.5 mg steps, but below 10 mg the rate should be slower and the steps each of 1 mg. Most patients will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long-term. Steroid-sparing immunosuppressive agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP.

Calcium and vitamin D supplements and sometimes bisphosphonates are necessary to prevent osteoporosis while high-dose steroids are being used (p. 556).

Takayasu's arteritis

This is a granulomatous inflammation of the aorta and its major branches and is discussed on page 789.

Medium-sized vessel vasculitis

Polyarteritis nodosa (PAN)

Classical PAN is a rare condition which usually occurs in middle-aged men. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features

These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.

- **Neurological:** mononeuritis multiplex is due to arteritis of the vasa nervorum.
- **Abdominal:** pain due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.

Systemic inflammatory vasculitis

FURTHER READING

Dasgupta B. Concise guidance: diagnosis and management of polymyalgia rheumatica. *Clin Med* 2010; 10:270–274.

- **Renal:** presents with haematuria and proteinuria. Hypertension and acute/chronic kidney disease occur.
- **Cardiac:** coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- **Skin:** subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur, but are uncommon.
- **Lung:** involvement is rare.

Investigations and treatment

- **Blood count.** Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy** material from an affected organ shows features listed above.
- **Angiography.** Demonstration of microaneurysms in hepatic, intestinal or renal vessels if necessary.
- **Other investigations** as appropriate (e.g. ECG and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.

Treatment is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.

Kawasaki's disease

This is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan, and an infective trigger is suspected. It occurs worldwide and is also seen in adults.

Clinical features and treatment

The clinical features are:

- Fever lasting 5 days or more
- Bilateral conjunctival congestion 2–4 days after onset
- Dryness and redness of the lips and oral cavity 3 days after onset
- Acute cervical lymphadenopathy accompanying the fever
- Polymorphic rash involving any part of the body
- Redness and oedema of the palms and soles 2–5 days after onset.

The persistent fever plus at least four of the other five features should be present to make the diagnosis, or fewer than four if coronary aneurysms can be seen on two-dimensional echocardiography, MRI or angiography.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis leading to aneurysms or dilatation. Other features include diarrhoea, albuminuria, aseptic meningitis and arthralgia and, in most, there is a leucocytosis, thrombocytosis and a raised CRP. Anti-endothelial cell autoantibodies are often detectable.

Treatment is with a single dose of high-dose intravenous immunoglobulin (2 g/kg), which prevents the coronary artery disease, followed after the acute phase by aspirin 200–300 mg daily. There is no evidence that steroid treatment improves the outcome.

Small vessel vasculitis

This can be separated into those that are positive or negative for anti-neutrophil cytoplasmic antibody (ANCA) (see p. 498).

- ANCA-positive small vessel vasculitis
 - Wegener's granulomatosis (see p. 847)
 - Churg–Strauss granulomatosis (see p. 847)
 - Microscopic polyangiitis (see p. 847)

- ANCA-negative small vessel vasculitis
 - Henoch–Schönlein purpura (see p. 627)
 - Cryoglobulinaemic vasculitis (see p. 581)
 - Cutaneous leucocytoclastic vasculitis (p. 1228).

Cutaneous leucocytoclastic vasculitis is the characteristic acute purpuric lesion which histologically involves the dermal post-capillary venules. This lesion affects only the skin and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia and glomerulonephritis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

Treatment of small cell vasculitis

The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment whereas involvement of major organs (e.g. lungs or kidneys in Wegener's granulomatosis) requires high-dose corticosteroids, immunosuppression and sometimes plasma exchange. Two recent clinical trials have shown that depletion of B cells with rituximab is as effective as cyclophosphamide in treating ANCA-associated vasculitis and it is likely that this will become a common form of treatment in the near future.

Behçet's disease

Behçet's disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100 000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele, with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

Clinical features

The cardinal clinical feature is recurrent oral ulceration. The international criteria for diagnosis require oral ulceration and any two of the following: genital ulcers, defined eye lesions, defined skin lesions, or a positive skin pathergy test (see below). Oral ulcers can be aphthous or herpetiform. The eye lesions include an anterior or posterior uveitis or retinal vascular lesions. Cutaneous lesions consist of erythema nodosum, pseudofolliculitis and papulopustular lesions.

Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia; pulmonary and renal lesions; thrombophlebitis (especially in the legs); vasculitis; a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The pathergy reaction is highly specific to Behçet's disease. Skin injury, by a needle prick for example, leads to papule or pustule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

Treatment

Corticosteroids, immunosuppressive agents and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities). Anti-TNF agents can be

Juvenile idiopathic arthritis	Other conditions
Systemic arthritis	Henoch–Schönlein purpura
Oligoarthritis (persistent)	Infections, e.g. tuberculosis, septic arthritis, viral arthritis

Psoriatic arthritis	SLE and other autoimmune rheumatic disease
Unclassified	Transient synovitis of the hip

Figure 11.31 The differential diagnosis of arthritis in children.

used to control severe uveitis and serious manifestations such as neurological and gastrointestinal Behçet's disease.

ARTHRITIS IN CHILDREN

Joint and limb pains are common in children but arthritis is fortunately rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. [Figure 11.31](#) summarizes the differential diagnosis.

For chronic conditions, the child and family often need a great deal of support from physiotherapists, occupational therapists, psychologists, teachers, social workers and orthopaedic surgeons. These are best obtained in specialist paediatric centres.

Juvenile idiopathic arthritis (JIA)

Systemic onset JIA

Still's disease (which accounts for 10% of cases of JIA) affects boys and girls equally up to 5 years of age; then girls are more commonly affected. Adult-onset Still's disease is extremely rare.

Clinical features include a high ($>39^{\circ}$) fever with an evanescent pink maculopapular rash and arthralgia, arthritis, myalgia and generalized lymphadenopathy. Hepatosplenomegaly, pericarditis and pleurisy occur. The differential diagnoses include malignancy, in particular leukaemia and neuroblastoma, and infection. Laboratory tests show a high ESR and CRP, neutrophilia and thrombocytosis. Autoantibodies are negative. Macrophage activation syndrome (an excessive proliferation of T cells and macrophages) is a rare but potentially fatal complication. It can follow infection (often viral) or a change in medication.

Oligoarthritis (persistent)

This is the most common form of JIA (50–60%) but is still a relatively uncommon condition. It affects, by definition, four or fewer joints, especially knees, ankles and wrists, often in an asymmetrical pattern. It affects mainly girls, with a peak age of 3 years. The prognosis is generally good with most going into remission. Uveitis (often with a positive ANA) occurs and requires regular screening by slit-lamp

examination. Blindness can occur if it is untreated. Prognosis is generally good, with remission occurring eventually in most patients.

Oligoarthritis (extended)

In approximately 25% of patients, oligoarthritis extends to affect many more joints after around 6 months. This form of arthritis can be very destructive.

Polyarthritis JIA

The *rheumatoid factor-positive* form (usually also ACPA positive) occurs in older girls, usually over 8 years. It is a systemic disease; the arthritis commonly involves the small joints of the hands, wrists, ankles and feet initially, and eventually larger joints. It can be a very destructive arthritis and needs aggressive treatment.

The *rheumatoid factor-negative* form is commoner. It usually affects girls under 12 years but can occur at any age. The arthritis is often asymmetrical, with a distribution similar to that seen in the RF-positive form. It may also affect the cervical spine, temporomandibular joints and elbows. Patients may be ANA positive, with a risk of chronic uveitis. All children must have regular ophthalmologic examination.

Enthesitis-related arthritis

This affects teenage and younger boys mainly, producing an asymmetrical arthritis of lower-limb joints and enthesitis. It is associated with HLA-B27 and a risk of iritis. It is the childhood equivalent of adult ankylosing spondylitis but spinal involvement is rare in childhood. Approximately one in three develops spinal disease in adulthood.

Psoriatic arthritis

This occurs in children and is similar in pattern to the adult form. The arthritis can be very destructive. Psoriasis may develop long after the arthritis but is found commonly in a first-degree relative.

Treatment of JIA

Early recognition and aggressive treatment prevents joint damage and allows normal growth and development. There is no cure but clinical remission is an achievable goal. JIA should always be referred to a specialist paediatric rheumatology unit with facilities to assess and design treatment plans which aim to prevent long-term disability. These units also need facilities for rehabilitation, education and surgical intervention. NSAIDs reduce pain and stiffness but disease-modifying agents such as methotrexate are used to control moderate and severe disease. Corticosteroids are often required in systemic disease: intravenous pulsed methylprednisolone is used, followed by methotrexate (10–15 mg/m²) weekly to control disease and prevent growth suppression.

Cytokine modulators (see [Table 11.16](#)) are used if methotrexate fails, and are highly effective in all types except systemic-onset JIA where the results are variable. Etanercept and adalimumab are the commonest drugs used but anakinra, tocilizumab and abatacept are being used in systemic-onset JIA. Anakinra ([p. 526](#)), an IL-1 β receptor antagonist, helps in methotrexate-resistant systemic onset disease. Sulfasalazine is used only in enthesitis-related JIA. Aspirin may be a cause of Reye's syndrome and should not be used under the age of 12 years.

Prognosis

Before cytokine modulators, up to 50% of children developed long-term disability; 25% continued to have active arthritis into adult years. Death was due to infection

or systemic disease with pericarditis or amyloidosis. The prognosis has much improved but long-term studies, particularly on safety, are awaited.

Other types

Henoch–Schönlein purpura (see also p. 583)

This is the commonest systemic vasculitis seen in children. Skin biopsy findings are pathognomonic, with IgA immune complexes deposit in the small vessels and leucocytotoxic vasculitis in host capillary venules. It often occurs after upper respiratory tract infections. Other manifestations include lower limb purpura, a transient non-migratory polyarthritis, and abdominal pain. Some 50% of these patients will have haematuria and proteinuria, due to a glomerulonephritis; treatment of this is discussed on [page 583](#). The prognosis is excellent, although 1% develop chronic renal damage.

Rheumatic fever

Rheumatic fever still occurs occasionally in developed countries but is more common in developing countries. It is described on [page 127](#).

The arthritis affects large joints and migrates between joints, each being affected for a few days at a time. This is unlike systemic onset JIA, where arthritis is usually much more persistent in each affected joint. The fever is persistent but rarely as high as in systemic onset JIA, and the temperature often remains above normal. A child may not volunteer a history of sore throat and the carditis may be silent. Isolated arthritis is the presenting symptom in 14–42%. The disease is easily missed if not included in the differential diagnosis of acute childhood arthritis.

Treatment is described on [page 128](#).

Hypermobility syndrome

Around 5–10% of children are hypermobile. A proportion of them will develop various musculoskeletal complaints in early childhood, such as late walking, flat feet or nocturnal leg pains, probably due to hypermobile ankles and knees suffering recurrent sprains and strains after exercise. Joint effusions, subluxation, dislocation and ligamentous injuries may occur throughout childhood. Low back pain may develop in affected adolescents. There is a risk of the early development of osteoarthritis in adulthood. More severe hypermobility is also seen in Ehlers–Danlos and Marfan's syndromes (see [pp. 743](#)) and in the joint hypermobility syndrome.

Treatment is with exercise directed at improving the strength of muscles that cross affected joints, as well as overall fitness and endurance. It may be necessary to reduce or change sporting and other activities. Cognitive behavioural therapy helps in teenagers.

Miscellaneous conditions

Idiopathic musculoskeletal pain can become chronic in children. Management requires exclusion of the causes shown in [Figure 11.31](#), but without performing unnecessary laboratory investigations. Nocturnal musculoskeletal pains are episodic and may be associated with hypermobility. They are called 'growing pains'. They often last 15–30 minutes and awaken the child from sleep, and may require physiotherapy and analgesics, together with advice and support to the parents.

Low back pain in children may reflect psychosocial problems at home or school as much as any obvious musculoskeletal pathology.

Osteochondritis can affect the ossification centre of the ends of bones. A typical condition is *Osgood–Schlatter disease*, which is characterized by localized pain and swelling over the tibial tubercle or at the patellar tendon insertion. It is usually seen in athletic teenagers and responds to local treatment and changes of sporting activities. Sever's disease is an osteochondritis of the insertion of the Achilles tendon into the calcaneum.

Perthes' disease is an idiopathic, possibly avascular, necrosis of the proximal femoral epiphysis, of unknown aetiology. It presents as a painless limp, usually in boys aged 3–12 years, and is occasionally bilateral. If severe it may require surgical correction.

Transient synovitis of the hip (irritable hip) causes painful limitation of movement, usually of one hip, after an upper respiratory infection in young children (usually boys). Symptoms usually resolve within a few weeks (2–3% develop Perthes' disease) but other more serious causes of hip pain should be excluded. Treatment is with rest and analgesia until the pain resolves.

RHEUMATOLOGICAL PROBLEMS SEEN IN OTHER DISEASES

Gastrointestinal and liver disease

- **Enteropathic synovitis.**
- **Autoimmune hepatitis** (see [p. 326](#)) may be accompanied by an arthralgia similar to that seen in systemic lupus erythematosus. Joint pain occurs in a bilateral, symmetrical distribution, with the small joints of the hands being predominantly affected. Joints usually look normal but sometimes there is a slight soft tissue swelling. These patients often have positive tests for antinuclear antibodies.
- **Primary biliary cirrhosis** patients occasionally have a symmetrical arthropathy.
- **Hereditary haemochromatosis** is associated with arthritis in 50% of cases; this is often the first sign of the disease and chondrocalcinosis is common.
- **Whipple's disease** (see [p. 268](#)) is accompanied by fever and arthralgia.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting, worse at night and there are other clinical clues such as weight loss or ill-health. Secondary gout occurs in conditions such as chronic myeloid leukaemia.

Neoplastic disease of bone

Malignant tumours of bone are shown in [Table 11.21](#). The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and usually seen only in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and are occasionally related to hypercalcaemia (see [p. 544](#)). The diagnosis of metastases can often be made from the history and examination, particularly if the primary tumour has

already been diagnosed. Symptoms from bony metastases may, however, be the first presenting feature.

Investigations

- **Skeletal isotope scans** show bony metastases as 'hot' areas before radiological changes occur.
- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **MRI** is used extensively, particularly for vertebral lesions.
- **CT and CT-PET** are useful.
- **Serum alkaline phosphatase** (from bone) is usually raised.
- **Hypercalcaemia** is seen in 10–20% of patients who have metastatic malignancies or is due to ectopic parathormone or parathyroid hormone-related protein secretion.
- **Prostate-specific antigen (PSA)** and serum acid phosphatase are raised in the presence of prostatic metastases.

Treatment

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Bisphosphonates (p. 555) can help symptomatically. Occasionally, pathological fractures require internal fixation.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic osteoarthropathy is most often associated with carcinoma of the bronchus. It is a paraneoplastic, non-metastatic complication and may be the presenting feature of the disease. It occurs only rarely with other conditions that also cause clubbing. It is seen most often in middle-aged men, who present with pain and swelling of the wrists and ankles. Other joints are involved occasionally. The mechanism is unclear. One suggestion is the release of vascular endothelial growth factor (VEGF) into the circulation. Primary HPO is a hereditary condition involving a mutation in the HPGD gene that degrades prostaglandin E_2 (PGE_2). The mutation therefore allows over-production of PGE_2 , which may cause clubbing.

The diagnosis is made on the presence of clubbing of the fingers, which is usually gross, and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

Treatment should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

Paraneoplastic polyarthritis

This is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

Skin disease**Psoriatic arthritis**

This is discussed on page 528.

Erythema nodosum (see p. 1216)

This is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

Neurological disease

Neuropathic joints (Charcot's joints) are joints damaged by trauma as a result of the loss of the protective pain sensation. They were first described by Charcot in relation to tabes dorsalis. They are also seen in syringomyelia, diabetes mellitus and leprosy. The site of the neuropathic joint depends upon the localization of the pain loss:

- In tabes dorsalis, the knees and ankles are most often affected.
- In diabetes mellitus, the joints of the tarsus are involved.
- In syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement. This is associated with neurological findings that depend upon the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

Treatment is symptomatic. Surgery may be required in advanced cases.

Blood disease

Arthritis due to haemarthrosis is a common presenting feature of people with *haemophilia* (see p. 411). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

Sickle cell crises (p. 408) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 556) and by osteomyelitis.

Arthritis can also occur in *acute leukaemia*; it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

Individuals with *thalassaemia major* (see p. 374) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures due to osteoporosis. There is marked discal calcification.

Endocrine and metabolic disorders

Hypothyroid patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

Hyperparathyroidism may be complicated by chondrocalcinosis and acute pseudogout.

In **acromegaly**, arthralgia occurs in about 50% of patients. It particularly affects the small joints of the hands and knees. There may be carpal tunnel syndrome.

In **Cushing's disease**, back pain is common.

Joint disorders related to *diabetes mellitus* are described on page 1026.

Familial hypercholesterolaemia is associated with oligo- or polyarthritis usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

MISCELLANEOUS ARTHROPATHIES

Familial Mediterranean fever (FMF)

FMF is inherited as an autosomal recessive condition and occurs in certain ethnic groups, particularly Arabs, Turks, Armenians and Sephardic Jews. The gene, called *MEFV*, has been localized to chromosome 16. It encodes for pyrin (or marenostrin), a suppressor of the activation of caspase 1, which stimulates the biosynthesis of interleukin-1 β , which drives inflammation. Failure of suppression leads to FMF attacks.

These are characterized by recurrent attacks of fever, arthritis and serositis. Abdominal or chest pain due to peritonitis or pleurisy occurs. The arthritis is usually monoarticular and attacks last up to 1 week. The CRP is markedly raised during the attacks. The condition may be mistaken for palindromic rheumatism (p. 519), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but usually it is based on the clinical picture and exclusion of other conditions.

Treatment. Regular colchicine 1000–1500 μ g daily can usually prevent the attacks. In resistant patients, thalidomide (p. 445) and anakinra can be tried. In general, the disorder is benign but in 25% of cases, renal amyloidosis develops.

Sarcoidosis

Sarcoidosis (see p. 847) is a multisystem granulomatous disease and is associated with erythema nodosum, which occurs in 20% of cases at or soon after the onset of the disease. The most useful diagnostic test is a chest X-ray, which shows hilar lymphadenopathy in 80% of cases. The serum ACE may be raised.

Other patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout. Bone cysts can also develop.

Treatment is with NSAIDs, but if these fail to control the symptoms, corticosteroids are usually very effective.

SAPHO (Synovitis, Acne, Palmoplantar pustulosis, Hyperostosis, Osteitis)

This rare syndrome appears to be a reaction to chronic *Propionibacterium acnes* infection. It produces chronic multifocal osteitis with anterior chest wall pain and peripheral synovitis. There is inflammatory cytokine release and global neutrophil activation. Etanercept (p. 524) may help.

Osteochondromatosis

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

Treatment involves removal of loose bodies and synovectomy.

Pigmented villonodular synovitis

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.

Treatment is synovectomy or radiotherapy. In tendon sheaths, the condition gives rise to a nodular mass that requires excision.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

Treatment involves corticosteroids and immunosuppressive agents.

DISEASES OF BONE

Bone is a specialized connective tissue serving three major functions:

- **Mechanical** – structure and muscle attachment for movement
- **Metabolic** – providing the body's primary store of calcium and phosphate
- **Protective** – enclosing the marrow and other vital organs.

STRUCTURE AND PHYSIOLOGY

(Fig. 11.32)

Bone structure

Bone is comprised of cells and a matrix of organic protein and inorganic mineral. Long bones (femur, tibia,

Figure 11.32 Diagram of a longitudinal section of a growing long bone.

humerus) and flat bones (skull, scapula) have different embryological templates, with varying proportions of cortical and trabecular bone.

- **Cortical (compact) bone** forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is particularly adapted to withstand bending strain.
- **Trabecular (cancellous) bone** is found at the ends of long bones and inside flat bones. Comprised of a network of interconnecting rods and plates of bone, it offers resistance to compressive loads. It is also the main site of bone remodelling for mineral homeostasis.
- **Woven bone** lacks an organized structure. It appears in the first few years of life, at sites of fracture repair and in high-turnover bone disorders such as Paget's disease.
- **Lamellar bone**, in which the collagen fibres are arranged in parallel bundles, forms the bone in adult life.

Matrix components

Type I collagen is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical bone, concentric lamellae form around a central blood supply (Haversian system) which communicates via transverse (Volkmann's) canals. Non-collagen proteins include osteopontin, osteocalcin and fibronectin. Bone mineral largely consists of calcium and phosphate in the form of hydroxyapatite.

Bone cells

Osteocytes

These are small cells, derived from osteoblasts, embedded in bone and interconnected with each other and with bone lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered

cell signalling, which in turn activates bone formation with or without prior resorption.

Osteoblasts

Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis, others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts critically regulate bone resorption through the balance in expression of the stimulatory RANKL (the ligand for receptor activator of nuclear factor kappaB) and its antagonist, osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors for PTH, oestrogen, glucocorticoids, vitamin D, inflammatory cytokines and the transforming growth factor- β family, all of which may therefore influence bone remodelling.

Osteoclasts

These are cells with the unique capacity to resorb bone and are derived from haematopoietic precursors of the macrophage lineage. In response to RANKL and macrophage colony stimulating factor (M-CSF), they attach to bone, creating a ruffled border which forms a number of extracellular lysosomal compartments. Hydrogen ions are actively secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g. cathepsin K) resorb the collagen matrix.

Bone growth and remodelling

Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis (Fig. 11.32). Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at between 18 and 21 years when the epiphysis and metaphysis fuse.

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. Signals regulating initiation of remodelling include changes in osteocytes (apoptosis or altered signalling of sclerostin, prostaglandins and other molecules), resulting in altered balance of RANKL and OPG expression by adjacent osteoblasts. Regulation of bone formation involves reciprocal effects of *wnt* versus *dickkopf* (*Dkk*) and sclerostin on the LRP5/6- β -catenin pathway.

Remodelling is carried out by the *basic multicellular unit* (BMU) (Fig. 11.33). Retraction of bone lining cells precedes binding of multinucleate osteoclasts to the bone surface, resulting in bone resorption. Unknown factors limit the amount of bone resorbed, after which osteoblasts fill in the resorption cavity. Bone remodelling is said to be coupled as formation normally follows resorption. New bone formation without resorption may, however, occur in the adult skeleton in response to anabolic therapy such as parathyroid hormone peptides. Additional influences include systemic hormones of which oestrogen (in both sexes) is particularly involved, promoting survival of osteocytes and inhibiting osteoclastogenesis.

CALCIUM HOMEOSTASIS AND ITS REGULATION

Calcium homeostasis is regulated by the effects of parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D ($1,25(\text{OH})_2\text{D}_3$) on gut, kidney and bone. Calcium-sensing

Xiong J, Onal M, Jilka RL, et al. Matrix-embedded cells control osteoclast formation. *Nat Med* 2011; 17:1235–1241.

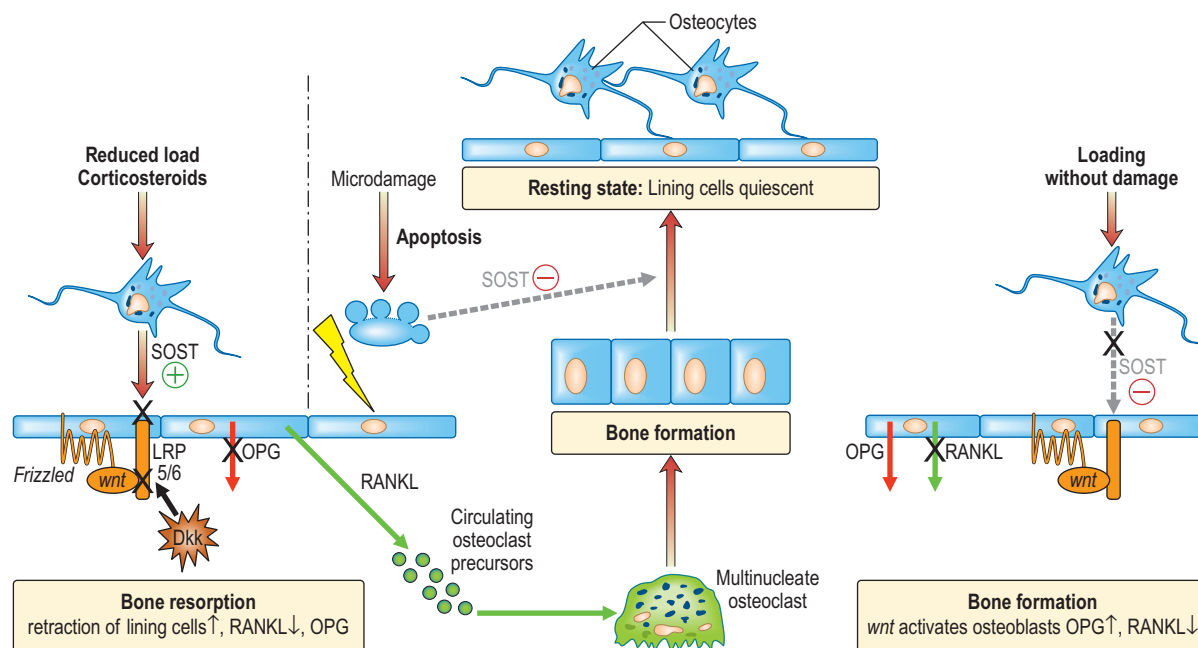

Figure 11.33 Bone is remodelled in response to alterations in two reciprocal systems. Quiescent bone (centre), may experience **reduced load** (left); in response, the osteocyte increases expression of sclerostin (SOST⁺), inhibiting the response to *wnt* via the LRP5/frizzled co-receptor complex (orange). **Microdamage** (left) causes osteocyte apoptosis, with direct osteoclast-generating effects via RANKL, and loss of the inhibitory effect of SOST on later bone formation (dashed line, SOST⁻). The osteoblastic lining cells retract from an area of bone, forming a bone remodelling unit, while increased expression of RANKL and reduced osteoprotegerin (OPG) activates formation of a bone-resorbing multinucleate osteoclast from circulating precursors; the resorbed area is then replaced by new osteoid formed by cuboidal osteoblasts. As new osteocytes are formed, SOST levels rise and the osteoblasts cease formation, the majority undergoing apoptosis. If bone experiences **loading without damage** (right), sclerostin expression is reduced (SOST⁻), increasing signal response to *wnt*, activation of osteoblast bone formation, and increased OPG expression. Anabolic therapy with PTH is likely to act in a similar fashion. **Corticosteroids** may increase osteocyte SOST expression, and stimulate expression of *Dkk*, another inhibitor of the *wnt*/LRP5/frizzled axis. **Myeloma cells** have dual lytic effects, with enhanced expression of RANKL and expression of *Dkk*. In **rheumatoid arthritis**, similarly, RANKL and *Dkk* are increased, whereas in **spondyloarthritis**, characterized by new bone formation alongside erosion, *Dkk* is inhibited, with the increased *wnt* activity also increasing OPG relative to RANKL.

receptors are present in the parathyroid glands, kidney, brain and other organs.

Calcium absorption and distribution

Daily calcium consumption (Fig. 11.34), primarily from dairy foods, should ideally be around 20–25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to bone fragility in some older persons. Intestinal absorption of calcium is reduced by vitamin D deficiency, and in malabsorption states.

Vitamin D metabolism

The primary source of vitamin D (Fig. 11.35) in humans is photoactivation in the skin of 7-dehydrocholesterol to cholecalciferol, which is then converted first in the liver to 25-hydroxyvitamin D (25(OH)D₃) and subsequently in the kidney (by the enzyme 1 α hydroxylase) to 1,25(OH)₂D₃. Regulation of the latter step is by PTH, phosphate and feedback inhibition by 1,25(OH)₂D₃.

Parathyroid hormone (PTH)

PTH, an 84 amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which bear calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by:

- increasing osteoclastic activity (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1 α -hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

Calcitonin

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

INVESTIGATION OF BONE AND CALCIUM DISORDERS (Table 11.22)

Total plasma calcium (2.2–2.6 mmol/L)

About 40% is ionized and physiologically active: the remainder is complexed or protein bound. As ionized calcium is difficult to measure, normal practice is to measure total

calcium, correcting the value to allow for protein binding according to the following formula: add or subtract 0.02 mmol/L for each gram per litre of a simultaneous albumin level below or above 40 g/L. For critical measurements, samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma calcium concentration).

Plasma phosphate (0.8–1.4 mmol/L)

Phosphate is essential to most biological systems. High levels are found in renal failure and hypoparathyroidism, while low levels are associated with primary hyperparathyroidism, hypophosphataemic rickets and osteomalacia and other disorders associated with reduced renal tubular phosphate reabsorption.

Plasma PTH (reference range 10–65 ng/mL, need to check with your local laboratory)

The PTH assay measures the intact hormone. In hypercalcaemia due to causes other than hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels, and in familial hypocalciuric hypercalcaemia (FHH) serum PTH may be normal or marginally elevated.

Serum 25-hydroxyvitamin D (deficiency <25 nmol/L (10 ng/mL) insufficiency <75 nmol/L (30 ng/mL))

Vitamin D status is best assessed using serum 25-(OH) D_3 , as 1,25(OH) $_2D_3$ has a short half-life and does not accurately reflect true vitamin D status. Levels are only measured if disorders of vitamin D metabolism are suspected. Whilst rickets and osteomalacia occur with vitamin D deficiency, vitamin D insufficiency may increase the risk of a wide range

of conditions, including ischaemic heart disease and a number of cancers.

24-hour urinary calcium (normal range 2.5 up to 6.25 (female) and 7.5 (male) mmol/24 h)

This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception is familial hypocalciuric hypercalcaemia where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be performed in the assessment of hypercalcaemic patients.

Biochemical markers of bone formation and resorption

While these are available in many laboratories, their use is limited by large biovariability and measurement variance.

Figure 11.34 Calcium exchange in the normal human. The amounts are shown in mmol per day.

Figure 11.35 The metabolism and actions of vitamin D. 1,25-Dihydroxycholecalciferol (calcitriol) is the biologically active agent. It inhibits 1 α -hydroxylase and stimulates 24-hydroxylase to produce 24,25-dihydroxy- D_3 , which is not biologically active. FGF, fibroblast growth factor secreted by osteocytes. CYP, cytochrome P enzyme.

Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases. In addition, measurements of bone turnover markers may have a role in the assessment of fracture risk.

- **Bone-specific alkaline phosphatase.** Circulating alkaline phosphatase is derived from bone, liver and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth, fracture repair, and in high bone turnover states.
- **Type 1 collagen propeptides** are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) propeptides reflect bone formation.
- **Serum osteocalcin** is another bone formation marker.
- **Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides** reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states.

Diagnostic imaging

- **Plain radiographs** identify fractures, tumours and infections. Other specific features may be seen (see following sections).
- **Radionuclide imaging.** Technetium-99m-labelled methylene bisphosphonate uptake in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fractures, tumour and metastatic deposits, infection and Paget's disease of bone.
- **Magnetic resonance imaging** is the most sensitive and specific test for the diagnosis of osteomyelitis. It is also useful in the detection of stress fractures, which may not be demonstrated on plain radiographs. A technique to suppress the high signal associated with bone marrow (such as STIR sequences, see p. 498) allows highly sensitive recognition of 'bone marrow oedema', a nonspecific feature of a number of bone disorders including avascular necrosis. High-resolution MRI provides information about bone microarchitecture, but this is not yet applied in the clinical setting.
- **Bone biopsy** (Fig. 11.36). A core of bone is removed, including both cortices of the iliac crest, using a trephine. The non-decalcified specimen is examined for static and dynamic (bone turnover) indices. An oral tetracycline is given to the patient prior to the biopsy, for 2 days on two occasions 10 days apart, allowing assessment of the rate of bone turnover and mineralization. Biopsy is most commonly used in assessment of suspected renal bone disease and osteomalacia.
- **Bone densitometry measurements** (p. 553).

OSTEOPOROSIS**Definition and incidence**

Osteoporosis is defined as 'a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk'.

Figure 11.36 Computerized images of bone biopsies in osteoporosis demonstrate changes in bone architecture over time. *Upper pair* without treatment, the bone cortex becomes thinner, and numerous trabecular rods and plates are lost. *Centre pair* in response to bisphosphonate treatment, resorption is reduced, with preservation of bone mineral and structure. *Lower pair* in response to anabolic therapy, bone is increased at both trabecular and cortical sites. (From Jiang Y, Zhao JJ, Mitlak BH et al. Recombinant human parathyroid hormone (1–34) improves both cortical and cancellous bone structure. *Journal of Bone and Mineral Research* 2003; 18: 1932–1941, with permission of the American Society for Bone and Mineral Research.)

The World Health Organization (WHO) defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T-score ≤ -2.5) or lower. Values between -1 and -2.5 SDs below the young adult mean are termed 'osteopenia'. The rationale for this definition is the inverse relationship between bone mineral density and fracture risk in postmenopausal women and also older men. However, this definition should not be applied to younger women, men or children.

Figure 11.37 Lifetime changes in bone mineral density (BMD). Peak bone mass is achieved between 20 and 30 years of age (gain), and consolidated up to around the age of 40 years. Then, age-related bone loss occurs in both men and women, with an accelerated loss in women starting around the time of menopause which lasts between 5 and 10 years.

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations, with osteoporotic fractures of the spine causing acute pain or deformity and postural back pain. One in two women and one in five men aged 50 years will have an osteoporotic fracture during their remaining lifetime. Caucasian and Asian races are particularly at risk. As the risk of fracture increases exponentially with age, changing population demographics will increase the burden of disease.

Pathogenesis

Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts leading to loss of bone mass.

Bone mass decreases with age (Fig. 11.37) but will depend on the 'peak' mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass, but multiple genes are involved, including collagen type 1A1 (p. 494), vitamin D receptor and oestrogen receptor genes. Nutritional factors, sex hormone status and physical activity also affect peak mass.

Risk factors

Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism are pathogenic factors.

Additional risk factors are associated with increased bone loss, or with increased bone fragility but are independent of effects on the bone mineral density (Table 11.23). For example, hyperparathyroidism, hyperthyroidism and malabsorption each increase the risk of the person having a low bone mass and are BMD dependent. However, other risk factors such as previous fracture, increasing age, glucocorticoid therapy, smoking and falls increase the risk of fracture, on top of the risk associated with their particular low bone mass. The effect of many of these risk factors is particularly notable in terms of hip fracture risk.

Treatment also can depend on the type of risk factors, for if they are recognized as 'skeletal', they respond to bone-directed treatment and if as 'non-skeletal', they require other intervention (e.g. reduction of falls risk).

Not all causes of osteoporosis affect bone remodelling and architecture in the same way. For example, oestrogen deficiency results in increased numbers of remodelling units, and increased resorption depth exceeding osteoblast synthetic

Table 11.23 Risk factors for fragility fractures

BMD-dependent	BMD-independent
Female sex	Increasing age
Caucasian/Asian	Previous fragility fracture
Gastrointestinal disease	Family history of hip fracture
Hypogonadism	Low body mass index
Immobilization	Smoking
Chronic liver disease	Excess alcohol use
Chronic kidney disease	Glucocorticoid therapy
Low dietary calcium intake	High bone turnover
Vitamin D insufficiency	Increased risk of falling
Chronic obstructive pulmonary disease	Rheumatoid arthritis

capacity, with a loss of resistance to fracture that is not fully reflected in the bone density measurement. Glucocorticoids induce a high turnover state initially, with increased fracture risk evident within three months of starting therapy. More prolonged use leads to a reduced turnover state but with a net loss due to reduced synthesis (through increased inhibition of the *wnt*-LRP5/6 axis).

Clinical features

Fracture is the only cause of symptoms in osteoporosis. Sudden onset of severe pain in the spine, often radiating around to the front, suggests *vertebral crush fracture*. However, only about one in three vertebral fractures is symptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance follow crushed vertebrae. *Colles' fractures* typically follow a fall on an outstretched arm. *Fractures of the proximal femur* usually occur in older individuals falling on their side or back. Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

Investigations

Plain radiographs usually show a fracture and may reveal previously asymptomatic vertebral deformities. Such clinically silent fractures may also be detected during the DXA scan with an additional analysis (called *lateral vertebral assessment*, Fig. 11.38) carried out with a much lower radiation dose than conventional imaging.

Bone density

- **Dual energy X-ray absorptiometry (DXA)** measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise, accurate, uses low

Figure 11.38 Vertebral fracture as seen on lateral vertebral assessment (LVA) and plain radiograph.

(a) The LVA image shows a vertebra with reduced height, at T12.

(b) The radiograph shows a typical wedge compression fracture.

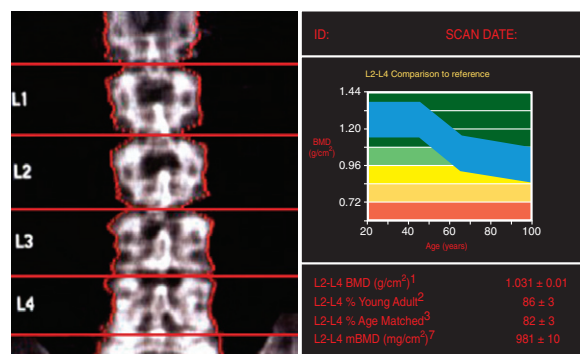

Figure 11.39 Dual energy X-ray absorptiometry of the lumbar spine. The AP image of the lumbar spine is shown on the left and on the right, the patient's value is expressed in relation to the reference range.

doses of radiation and is the 'gold standard' in osteoporosis diagnosis (Fig. 11.39). Because of osteophytes, spinal deformity and vertebral fractures, spinal values may be artefactually elevated and should be interpreted with caution in the elderly.

- **Quantitative ultrasound** of the calcaneum. This does not require ionizing radiation and is cheaper than other methods. It cannot be used for diagnostic purposes but is useful as a screening procedure prior to DXA assessment. The WHO T-score definition of osteoporosis should only be applied to DXA carried out at the hip and spine, and not to ultrasound, where a term such as 'low bone mass' is preferable.
- **Quantitative CT scanning** allows true volumetric assessment, and distinction between trabecular and cortical bone. However, it is more expensive, requires higher radiation than other techniques, and to date offers no clinical advantage.

Associated disease and risk factors

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be

Box 11.18 Management of osteoporosis: summary

Treatment is guided by risk of fracture, not BMD alone.

If intermediate risk from clinical factors, request DXA scan (see: www.shef.ac.uk/FRAX or other risk calculator until familiar with assessments).

Do not underestimate the risk from steroids or previous fracture.

Many guidelines (e.g. NICE) recommend bisphosphonate as first-line drugs in most cases.

Other options include:

- strontium ranelate or denosumab:
 - in young (to defer bisphosphonate use)
 - new fracture on a bisphosphonate or a fall in BMD or bisphosphonate use for 5–10 years
- teriparatide if multiple vertebral fractures or high risk
- i.v. zoledronate after hip fracture

BMD monitoring is required in:

- selected high-risk cases
- low-risk cases not treated

performed and are particularly necessary in men, in whom secondary causes are more common (Table 11.23).

Selection of individuals for treatment: risk assessment

The purpose of treatment is to reduce the risk of fractures (Box 11.18). Thus, assessment of absolute fracture risk should be made in every case. Although bone mineral density measurements in the spine and proximal femur provide useful information about fracture risk, they have a relatively low sensitivity and the majority of fragility fractures occur in women with a T-score ≥ -2.5 . Prediction of fracture risk can be improved by the addition of risk factors that are at least partially independent of bone mineral density (Table 11.23). This forms the basis of a 'fracture risk tool' for clinical practice that has been developed under the auspices of the WHO, which provides an algorithm for calculation of 10-year fracture probabilities, based on independent clinical risk factors with and without bone mineral density values. The intervention threshold can then be determined by the cost-effectiveness of treatment and by clinical judgement.

Table 11.24 Indications for DXA scanning

Radiographic osteopenia
 Previous fragility fracture (in those aged <75 years)
 Glucocorticoid therapy (in those aged <65 years)
 Body mass index below 19 (kg/m²)
 Maternal history of hip fracture
 BMD-dependent risk factors in Table 11.23

In patients presenting with height loss and/or kyphosis, lateral thoracic spine X-ray should be the initial investigation.

Figure 11.40 A graph illustrating the combined effects of age (x-axis) and reduced bone mass (expressed as T-scores on the z-axis) on the 10-year probability of fracture (y-axis) in a population of women. Reduced bone mass osteopenia, T-scores between -1 and -2.5. Osteoporotic bone (T-scores <-2.5) is shown in pale green. Note that the risk of fracture may be greater in an older woman with osteopenia than in a young woman with osteoporosis. (Data from Kanis JA. *Diagnosis of osteoporosis and assessment of fracture risk*. Lancet 359:1929–1936.)

All postmenopausal women and older men with a history of fragility fracture should be reviewed for treatment. In those aged >75 years, DXA is often not necessary prior to treatment but in those <75 years, DXA is useful in guiding treatment decisions (Table 11.24). However, other risk factors should also be taken into account when deciding whether to treat, particularly age and a history of previous fracture. Thus individuals with higher BMD values but with other clinical risk factors have a greater fracture probability than those with low BMD values in the absence of risk factors (Fig. 11.40).

Prevention and treatment

- **Symptomatic management.** New vertebral fractures may require bed rest for 1–2 weeks with strong analgesia, muscle relaxants (e.g. diazepam 2 mg three times daily) and gradual physiotherapy to restore confident mobilization (p. 505). Intravenous pamidronate helps severe pain. Non-spinal fractures should be treated by conventional orthopaedic means.
- **Calcium and vitamin D.** Daily intakes of 800–1000 mg of calcium and 400–800 IU of vitamin D are recommended, throughout life. Vitamin D and calcium supplements should also be given to patients receiving bone protective medication. Calcium given with vitamin D has been shown to reduce non-vertebral fractures, including hip fractures, in elderly women living in residential care (but not in those living in the community).

Table 11.25 Medications to reduce fracture risk in postmenopausal women

Intervention	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronate	+	+	+
Etidronate	+	ND	ND
Ibandronate	+	+ ^a	ND
Raloxifene	+	ND	ND
Risedronate	+	+	+
Strontium ranelate	+	+	+ ^a
Zoledronate	+	+	+
Denosumab	+	+	+
Teriparatide	+	+	ND
PTH (1–84)	+	ND	ND

^aDemonstrated only in high-risk subgroup. ND, not demonstrated.

- **Lifestyle measures.** Weight-bearing exercise for 30 minutes three times a week may increase BMD, while gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling. Smoking is associated with lower BMD and increased fracture risk. Excess alcohol use (>3 units/day) should be avoided.
- **Reduction of falls.** Physiotherapy and assessment of home safety are helpful. Hip protectors do reduce fractures in the elderly in residential care when worn correctly, but compliance is poor.

Pharmacological intervention (Fig. 11.36)

Most interventions used act by inhibiting bone resorption (anti-resorptives) although parathyroid hormone peptides stimulate bone formation. The mechanism of action of strontium ranelate remains incompletely defined.

The evidence base for *anti-fracture efficacy* of interventions varies. Adequately powered randomized controlled trials, with fracture as the primary endpoint, exist for alendronate, risedronate, ibandronate, zoledronate, raloxifene, hormone replacement therapy, strontium ranelate, denosumab, teriparatide (recombinant human PTH peptide 1–34), human recombinant parathyroid hormone 1–84 and combined calcium/vitamin D (the latter in frail older individuals only).

Some interventions have been shown to reduce fracture at vertebral and non-vertebral sites, including the hip, whereas others have not been demonstrated to be effective at all sites (Table 11.25). Since a fracture at one site increases the risk of subsequent fracture at any site, treatments with efficacy at all major fracture sites (particularly spine and hip) are preferable. Hence, the bisphosphonates and strontium ranelate are generally regarded as first-line options in the majority of postmenopausal women with osteoporosis.

- **Bisphosphonates**, synthetic analogues of bone pyrophosphate, adhere to hydroxyapatite and inhibit osteoclasts. Alendronate and risedronate are given most commonly as once weekly doses (70 mg and 35 mg, respectively) and zoledronate is given as a once yearly infusion of 5 mg. Ibandronate is available as a once monthly oral therapy (150 mg per month) or as a three-monthly intravenous injection (3 mg per 3 months). However, anti-fracture efficacy at non-vertebral sites has only been shown in high-risk subgroups with this latter choice.
- Oral bisphosphonates should be taken in the fasting state with a large drink of water, while the patient

Rachner TD, Khosla S, Hofbauer LC. Osteoporosis: now and the future. *Lancet* 2011; 377:1276–1287.

is standing or sitting upright. The patient should subsequently remain upright and avoid food and drink for at least 30 min.

- Bisphosphonates are generally well tolerated but may be associated with upper gastrointestinal side-effects such as oesophagitis, particularly if the dosing instructions are not closely followed. Bisphosphonates should be used with caution in patients who have chronic kidney disease (stage 4 or 5). Osteonecrosis of the jaw is rarely seen following high dose i.v. nitrogen-containing bisphosphonate in patients who have malignant disease. It is associated with poor dental hygiene. An association with bisphosphonate use in osteoporosis has not been clearly established.
- The optimal duration of bisphosphonate therapy is unknown; prolonged suppression of bone turnover may have adverse effects, including atypical femoral fractures, and it is currently advised to reassess treatment after 5–10 years, although benefits will frequently exceed the very low risk of these uncommon fractures.
- **Strontium ranelate** consists of two stable strontium atoms linked to an organic acid, ranelic acid. Its mechanism of action remains uncertain although it has weak anti-resorptive activity whilst maintaining bone formation. It reduces the risk of vertebral, hip and other non-vertebral fractures in postmenopausal women with osteoporosis. The dose is 2 g daily, given as granules dissolved in water at night. Nausea, diarrhoea and headaches are infrequent side-effects, and there is a small increase in the risk of venous thromboembolism.
- **Denosumab** is a fully human monoclonal antibody to RANKL. It is administered as a single subcutaneous injection every 6 months. Denosumab is an anti-resorptive agent which increases bone mineral density and reduces fractures at the spine, hip and other non-vertebral sites. Fracture risk reduction is equivalent to bisphosphonates. In addition to promoting osteoclastogenesis, RANKL has a role in the immune system and denosumab has been associated with exacerbations of eczema and a small increase in severe cases of cellulitis.
- **Raloxifene** 60 mg daily is a selective oestrogen-receptor modulator (SERM). It has no stimulatory effect on the endometrium but activates oestrogen receptors in bone. It prevents BMD loss at the spine and hip in postmenopausal women, though fracture rates were only reduced in the spine. It also reduces the incidence of oestrogen-receptor-positive breast carcinoma in women treated for up to 4 years. Leg cramps and flushing may occur and the risk of thromboembolic complications is also increased to a degree similar to that seen with HRT. Its use is associated with a small increase in the risk of stroke. Lasofoxifene is a new SERM undergoing clinical trials.
- **Recombinant human parathyroid hormone peptide 1–34 (teriparatide) and recombinant human parathyroid hormone 1–84** are anabolic agents that stimulate bone formation. *Teriparatide* reduces vertebral and non-vertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not available. It is given by daily subcutaneous injection in a dose of 20 µg for 18–24 months. *Recombinant human parathyroid hormone 1–84* is also administered by once daily subcutaneous

injection of 100 µg and has been only shown to reduce vertebral, but not non-vertebral fractures. An anti-resorptive drug should be given after parathyroid hormone peptide therapy to maintain the increase in bone mineral density. Non-osteoporotic bone diseases such as osteomalacia should be excluded prior to treatment. Parathyroid hormone peptide therapy is mainly indicated in severe cases of vertebral osteoporosis or in women who fail to respond to other therapies. *Teriparatide* causes only mild transient hypercalcaemia and routine monitoring is not required. Nausea and headache may occur. Recombinant human parathyroid hormone 1–84 is associated with a higher incidence of hypercalcaemia and hypercalciuria and routine monitoring is advised. Neither agent should be used in people with skeletal metastases or osteosarcoma.

- **Hormone replacement therapy (HRT)**. Because of adverse effects on breast cancer and cardiovascular disease risk, HRT is a second-line option for osteoporosis except in early postmenopausal women at high fracture risk who also have perimenopausal symptoms.
- **Calcitriol (1,25-(OH)₂D₃) and calcitonin** may reduce vertebral fracture rate, although the data are inconsistent.

Combination therapies, either with two anti-resorptive agents or an anti-resorptive and an anabolic agent, often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction than with monotherapy and combination therapy is not advised.

Glucocorticoid-induced osteoporosis

Individuals requiring continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for co-existing risk factors (age, previous fracture, hormone status). Postmenopausal women, men aged over 50 years and any individuals who have sustained a fragility fracture should receive treatment without waiting for DXA scanning. DXA results and fracture risk assessment guide treatment for other patients (Table 11.24). For these individuals, bisphosphonates and teriparatide are the approved agents. Calcium and vitamin D supplementation should also be given.

Osteoporosis in men

Alendronate and risedronate increase BMD and reduce vertebral fractures in men with osteoporosis. *Teriparatide* is also approved for use in this setting. In men with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone replacement is also used.

OSTEONECROSIS

This is also known as aseptic, avascular or ischaemic necrosis of the bone. The pathogenesis is uncertain but it is thought to result from a temporary interruption in the blood supply to the bone. There are a multitude of risk factors including glucocorticoid treatment, sickle cell disease, systemic lupus erythematosus (SLE), deep sea diving (Caisson's disease), endocrine disorders (e.g. Cushing's, diabetes mellitus), trauma, HIV infection, irradiation and excess alcohol use.

Osteonecrosis usually presents with joint pain but can be asymptomatic. If undiagnosed, it can lead to bone collapse.

MRI best confirms the diagnosis by showing bone marrow oedema. If advanced, it can be seen on plain X-rays. *Treatment* depends on the cause; joint replacement is often required. Risk may be reduced with statin therapy in steroid-associated osteonecrosis.

PAGET'S DISEASE

Osteitis deformans or Paget's disease is a focal disorder of bone remodelling. The initial event of excessive resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new bone is structurally abnormal.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget's disease is most often seen in Europe and particularly in northern England. It affects men and women (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. A positive family history is noted in about 14%.

Aetiology and pathogenesis

A number of genes have been implicated in Paget's disease, including nuclear factor kappa B (NF- κ B), sequestosome p62 (which results in activation of NF- κ B), osteoprotegerin and *6C12* (an anti-apoptotic gene). Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar microfilaments are seen in other bone disorders, and theories of a viral aetiology in Paget's remain contentious. Altered expression of *c-fos* (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100). Increased osteoclastic bone resorption is followed by formation of woven bone, which is weaker than normal bone, which leads to deformity and increased fracture risk. Unaffected bone remains normal throughout the disease course (i.e. Paget's disease does not spread, but can become symptomatic at previously silent sites).

Clinical features (Fig. 11.41)

Most (60–80%) people with radiologically identified Paget's disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polyostotic). The most common sites in order of frequency are pelvis, lumbar spine, femur, thoracic spine, sacrum, skull and tibia. Small bones of the feet and hands are rarely involved.

Symptoms include the following:

- Bone pain, most often in the spine or the pelvis
- Joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- Deformities, in particular bowed tibia and skull changes
- Neurological complications: nerve compression (deafness from VIIIth cranial nerve involvement; also cranial nerves II, V, VII may be involved); spinal stenosis; hydrocephalus due to blockage of the aqueduct of Sylvius
- High-output cardiac failure and myocardial hypertrophy due to increased bone blood flow
- Pathological fractures
- Osteogenic sarcoma in pagetic bone (fewer than 1% of cases, but a 30-fold increased risk compared with non-pagetic patients).

Investigations

- **X-ray** features (Fig. 11.41b) vary from predominantly lytic lesions (osteoporosis circumscripta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, thickening of trabeculae and loss of distinction between cortex and trabeculae (de-differentiation).
- **Isotope bone scans** show the extent of skeletal involvement, but are unable to distinguish between Paget's disease and sclerotic metastatic carcinoma (especially breast and prostate).
- **Increased serum alkaline phosphatase** with normal serum calcium and phosphate reflects increased bone turnover. Levels may be normal with limited or monostotic Paget's. Levels are reduced with treatment and increase during relapse. Mild hypercalcaemia follows immobilization only when there is extensive disease.
- **Urinary hydroxyproline** excretion is increased and may also be used as a marker of disease activity.

Treatment

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). Treatment is interrupted and repeat courses are guided by symptoms and by recurrence in elevation of alkaline phosphatase or urinary hydroxyproline. In addition to treating symptomatic patients, treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, e.g. fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

Intravenous bisphosphonates

Zoledronate is the most commonly used agent for Paget's disease, administered as a single infusion over 15 min. Pamidronate is an alternative but takes longer to infuse, is less potent and some patients develop drug resistance for unknown reasons. Both drugs can be associated with a first-dose reaction characterized by 'flu-like' symptoms, including transient pyrexia over 24–48 hours, which can be ameliorated with paracetamol.

Oral bisphosphonates

Oral bisphosphonates are typically used at doses higher than those for osteoporosis. They are less effective than zoledronate but at least as effective as pamidronate. Alendronate is given at a dose of 40 mg daily for 6 months, repeated after a further 6 months if necessary. Risedronate is given at a dose of 30 mg daily for 2 months, repeated after a further 2 months if necessary.

Surgery

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease (osteoarthritis). Intra-articular injection of lidocaine can be useful to differentiate joint or bone disease. Neurosurgery may be required where there is spinal disease. Osteosarcoma usually requires amputation, though

wide excision and limb-salvage can be successful at distal sites.

RICKETS AND OSTEOMALACIA

Osteomalacia is defective mineralization of newly formed bone matrix or osteoid. Rickets is defective mineralization at the epiphyseal growth plate and is found in association with osteomalacia in children.

Aetiology

Many factors can result in defective mineralization of the osteoid. For normal mineralization, adequate levels of vitamin D, calcium and phosphate, adequate activity of alkaline phosphatase, a normal pH at the osteoid surface and normal osteoid composition are all necessary (Table 11.26).

The most common cause of osteomalacia is hypophosphataemia due to hyperparathyroidism secondary to vitamin

D deficiency. The most common cause of vitamin D deficiency worldwide is dietary deficiency. Bread, milk and cereals in First World countries are now fortified with vitamin D. This has led to a greatly decreased incidence of osteomalacia and rickets.

Vitamin D is produced in the skin through the action of sunlight on 7-dehydrocholesterol (Fig. 11.35). Lack of sun exposure can lead to vitamin D deficiency, especially in individuals living in temperate regions who keep large parts of the skin covered throughout the year.

Vitamin D is a fat soluble vitamin so gastrointestinal disease can result in malabsorption of the vitamin. Gastrectomy, cystic fibrosis, coeliac disease, Crohn's disease and primary biliary cirrhosis are all well-recognized causes.

Due to the intimate involvement of the kidney in phosphate balance a number of causes of osteomalacia are mediated by the kidney. Primary renal phosphate wasting occurs in tumour-induced osteomalacia, multiple myeloma and the Fanconi's syndrome. Proximal (type 2) renal tubular acidosis can cause osteomalacia both due to renal phosphate wasting

Table 11.26 Causes of rickets/osteomalacia**Deficient intake or absorption of vitamin D**

Inadequate sun exposure or deficient synthesis in skin
Low dietary intake
Malabsorption: coeliac disease, Crohn's disease, gastrectomy, primary biliary cirrhosis

Defective 1- α -hydroxylation

Chronic kidney disease
Vitamin D-dependent rickets type I – due to deficiency of 1 α -hydroxylase

Primary renal phosphate wasting

Renal tubular acidosis (also by causing metabolic acidosis)
X-linked hypophosphataemia (vitamin D-resistant rickets or Dent's disease)
Fanconi's syndrome
Multiple myeloma
Tumour-induced osteomalacia

Inhibitors of mineralization

Fluoride, aluminium, bisphosphonates
Metabolic acidosis

Defective vitamin D receptors

Vitamin D-dependent rickets type II

and due to abnormal osteoid pH secondary to metabolic acidosis.

Clinical features

Osteomalacia may be asymptomatic and identified incidentally on routine investigations. When symptomatic it characteristically causes muscle weakness and widespread bone pain. Muscle weakness is due to a multifactorial proximal myopathy, with low vitamin D, hypophosphataemia and high PTH levels all contributing. It results in a characteristic waddling gait with difficulty climbing stairs and getting out of a chair. Generalized bone pain and tenderness is thought to be caused by hydration of the demineralized matrix; the resultant swelling pushes against the periosteum. The pain is typically a dull ache that is worse on weight-bearing and walking. It can be reproduced by pressure on the sternum or tibia. Insufficiency fractures can occur.

At birth, neonatal rickets may present as craniotabes (thin deformed skull). In the first few years of life, there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the 'rickety rosary', or a groove in the rib cage (Harrison's sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

Investigations

- **Serum alkaline phosphatase** is elevated in 90% of cases.
- **Low serum calcium, low phosphate and elevated PTH** are each present in approximately half of the cases.
- **Serum 25-(OH)D₃** is low, usually less than 25 nmol/L (10 ng/mL).
- **Serum FGF-23** is elevated in many people with tumour-induced osteomalacia.
- **Plain radiographs** demonstrate decreased bone mineralization. The characteristic finding in osteomalacia is Looser's pseudofractures. These are narrow radiolucent lines with sclerotic borders running perpendicular to the cortex. They can be found at any site but are most commonly seen in the femur and pelvis.
- **Tetracycline-labelled bone biopsy** is the gold standard diagnostic test. This is not practical in most clinical settings and is mainly used in research studies.

Treatment

Vitamin D replacement is the cornerstone of treatment. Treatment involves two stages: an initial loading stage to replenish body stores of vitamin D and a subsequent maintenance phase to avoid repeat deficiency. All patients should also receive supplementary calcium of 1000–1200 mg/day. In nutritional deficiency recommended initial replacement is with calciferol 50 000 units per week orally. The initial replacement dose should be continued for 3 months. Calciferol is also available as an intramuscular injection; two doses of 300 000 units are usually enough to replenish body stores. Adequacy of vitamin D replacement should be evaluated by re-assaying vitamin D levels, or PTH levels if initially abnormal. This should be followed by regular supplementation with 800–1000 units of vitamin D per day.

Doses for children are lower and are age dependent. People with gastrointestinal disease and vitamin D deficiency due to malabsorption need higher doses of 10 000–50 000 units per day of ergocalciferol.

Tumour-induced osteomalacia is best treated by removal of the causative neoplasm which is usually occult and frequently benign. This leads to rapid resolution of symptoms.

SKELETAL DYSPLASIAS

These include a large group of heterogeneous disorders of bone and connective tissue.

Collagen defects

Collagen is responsible for many of the structural, tensile and load-bearing properties in the various tissues where it is found. (The structure of collagen is discussed on page 494.) Thirty or more dispersed genes encode for more than 19 different types of collagen (Table 11.27).

Joint hypermobility syndrome

Joint laxity, which often starts in childhood (p. 546), can later produce widespread soft tissue lesions which are often caused initially by trauma. Mechanical back pain is common (p. 503). An arthralgia lasting over 3 months in 4 or more joints also occurs. The Beighton score (Box 11.19) is used in epidemiological studies to assess hypermobility.

Management is multidisciplinary, ensuring that the patient understands the nature of the problem so that injury can be prevented.

Ehlers–Danlos syndrome

This is a heterogeneous group of disorders of collagen. Ten different types have been recognized with varying degrees of skin fragility, skin hyperextensibility and joint hypermobility.

Types I, II and III are inherited in an autosomal dominant fashion; the biochemical basis is unknown. No abnormalities in *COL1A1*, *COL1A2* and *COL2A1* genes have been found.

Type IV (vascular type) is also autosomal dominant and involves arteries, the bowel and uterus, as well as the skin. Mutations in *COL3A1* gene produce abnormalities in structure, synthesis or secretion of type III collagen.

Type VI is a recessively inherited disorder and results from a mutation in the gene that encodes lysyl hydroxylase.

Type VII is an autosomal dominant disorder in which there is a defect in the conversion of procollagen to collagen; *COL1A1* and *COL1A2* mutations delete the N-proteinase cleavage sites.

Table 11.27 The major types of collagen

Collagen structure	Type number	Encoding gene	Associated conditions
Fibrillar	I, II, III, V, XI	COL1A1–2, COL2A2, COL3, COL5, COL11	Osteogenesis imperfecta, Ehlers–Danlos syndrome (subtypes)
Basement membrane	IV	COL4A1–5	Alport's syndrome (Chapter 12)
Fibril associated collagen with interrupted triple helix (FACIT)	IX, XII, XIV	COL9, 12, 14	
Filament-producing	VI	COL6A1–3	
Network-forming	VIII, X	COL8A1, 10A1	
Anchoring fibril	VII	Col7A1	Epidermolysis bullosa (p. 1223)

Box 11.19 The Beighton hypermobility score^a and diagnostic criteria for joint hypermobility syndrome

Joint	Finding	Score
Little (5th) finger	Passive dorsiflexion >90°	1 for each side
Thumb	Passive dorsiflexion to the flexor aspect of the forearm	1 for each side
Elbow	Hyperextends >10°, extends ≤10°	1 for each side
Knee	Hyperextends >10°, extends ≤10°	1 for each side
Forward flexion of trunk with the knees fully extended	Palms can rest flat on the floor	1

Diagnostic criteria for JHS: Beighton score ≥4; arthralgia for ≥3 months in ≥4 joints.
^aIn this 9-point system, the higher the score the higher the laxity. Young adults can score 4–6.

The other forms of Ehlers–Danlos are very rare and their defects have not been elucidated here. The clinical features are described on page 1229.

Osteogenesis imperfecta (fragilitas ossium, brittle bone syndrome)

This is a heterogeneous group of mainly autosomally dominant inherited disorders with mutations in *COL1A1*, *COL1A2* genes. There are four main types of osteogenesis imperfecta, and clinical subtypes are also described (V, VI and VII). The major clinical feature is bone fragility but other collagen-containing tissues are also involved, such as tendons, the skin and the eyes.

Type I: has mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints, and heart valve disorders

Type II: death in the perinatal period

Type III: severe bone deformity, blue sclerae

Type IV: fewer fractures, normal sclerae, normal lifespan.

Treatment with bisphosphonates (particularly intravenous pamidronate) has improved bone cortical thickness and skeletal development. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used.

Pearce SH, Cheetham TD. Diagnosis and management of vitamin D deficiency. *BMJ* 2010; 340:b5664.

Miscellaneous defects

Osteopetrosis (marble bone disease)

This condition may be inherited in either an autosomal dominant or a typically severe, autosomal recessive pattern. Another recessive form associated with renal tubular acidosis is due to carbonic anhydrase II deficiency.

The severe form is due to a mutation in the gene encoding a chloride channel necessary for osteoclast activity. Bone density is increased throughout the skeleton but bones tend to fracture easily. Encroachment on the marrow space leads to a leucoerythroblastic anaemia. There is mental retardation and early death. In the mild form there may be only X-ray changes, but fractures and infection can occur. The acid phosphate level is raised. Stem cell transplantation has been successful.

Marfan's syndrome

This is described on page 743.

Fibroblast growth factor receptor defect

Achondroplasia ('dwarfism') is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondral ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

FUNCTIONAL ANATOMY

The kidneys are paired organs, 11–14 cm in length in adults, 5–6 cm in width and 3–4 cm in depth. They lie retroperitoneally on either side of the vertebral column at the level of T12 to L3. The renal parenchyma comprises an outer cortex and an inner medulla. The functional unit of the kidney is the nephron, of which each contains approximately one million. Each *nephron* is made up of a glomerulus, proximal tubule, loop of Henle, distal tubule and collecting duct. The renal capsule and ureters are innervated via T10–12 and L1 nerve roots, and renal pain is felt over the corresponding dermatomes.

Renal arteries and arterioles

Arterial blood is supplied to the kidneys via the renal arteries, which branch off the abdominal aorta, and venous blood is conveyed to the inferior vena cava via the renal veins. Approximately 25% of humans possess dual or multiple renal arteries on one or both sides. The left renal vein is longer than the right and for this reason the left kidney, where possible, is usually chosen for live donor transplant nephrectomy.

The *renal artery* undergoes a series of divisions within the kidney (Fig. 12.1) forming successively, the *interlobar*

arteries, which run radially to the corticomedullary junction, *arcuate arteries*, which run circumferentially along the corticomedullary junction, and *interlobular arteries*, which run radially through the renal cortex towards the surface of the kidney. Afferent glomerular arterioles arise from the interlobular arteries to supply the glomerular capillary bed, which drains into *efferent glomerular arterioles*. Efferent arterioles from the outer cortical glomeruli drain into a peritubular capillary network within the renal cortex and then into increasingly large and more proximal branches of the renal vein. By contrast, blood from the juxtamedullary glomeruli passes via the vasa recta in the medulla and then turns back towards the area of the cortex from which the vasa recta originated.

Vasa recta possess fenestrated walls, which facilitates movement of diffusible substances. The collecting ducts merge in the inner medulla to form the ducts of Bellini, which empty at the apices of the papillae into the calyces. The calyces, in common with the renal pelvis, ureter and bladder, are lined with transitional cell epithelium.

The glomerulus

The *glomerulus* comprises four main cell types:

- Endothelial cells which are fenestrated with 500–1000 Å pores

Figure 12.1 Functional anatomy of the kidney. (a) The nephrons. (b) Arterial and venous supply. (After Standring S (ed) 2008 *Gray's Anatomy*, 40th edn. Edinburgh: Churchill Livingstone).

- Visceral epithelial cells (podocytes) which support the delicate glomerular basement membrane by means of an extensive trabecular network (foot processes)
- Parietal epithelial cells which cover the Bowman's capsule
- Mesangial cells (see Fig. 12.11).

Mesangial cells are believed to be related to macrophages of the reticuloendothelial system and have a phagocytic function and contractile capabilities that can control blood flow and filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the mesangial matrix, which provides a skeletal framework for the glomerular capillaries. The glomerular capillary *basement membrane* lies between the endothelial and the visceral epithelial cells. The latter put out multiple long foot processes which interdigitate with those of adjacent epithelial cells. Together the endothelial cells, basement membrane and epithelial cells form the *filtration barrier* or sieve (see Fig. 12.12a).

Renal tubules

The *renal tubules* are lined by epithelial cells, which are cuboidal except in the thin limb of the loop of Henle where they are flat. Proximal tubular cells differ from other cells of the system as they have a luminal brush border. The cortical portion of the collecting ducts contains two cell types with different functions, namely principal cells and intercalated cells (see p. 561). Fibroblast-like cells in the renal cortical interstitium have been shown to produce erythropoietin in response to hypoxia (p. 567).

The juxtaglomerular apparatus

The *juxtaglomerular apparatus* comprises the macula densa, the extraglomerular mesangium and the terminal portion

of the afferent glomerular arteriole (which contains renin-producing granular cells) together with the proximal portion of the efferent arteriole. The macula densa is a plaque of cells containing large, tightly packed cell nuclei (hence the name macula densa; see Fig. 12.2) within the thick ascending limb of the loop of Henle. This anatomical arrangement is such as to allow changes in the renal tubule to influence behaviour of the adjacent glomerulus (tubuloglomerular feedback).

RENAL FUNCTION

Physiology

A conventional diagrammatic representation of the nephron is shown in Figure 12.2a and a physiological version in Figure 12.2b.

An essential feature of renal function is that a large volume of blood – 25% of cardiac output or approximately 1300 mL/min – passes through the two million glomeruli.

A *hydrostatic pressure gradient* of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular capillary wall into Bowman's space and so into the renal tubule (Fig. 12.3).

The *ultrafiltration rate* (glomerular filtration rate; GFR) varies with age and sex but is approximately 120–130 mL/min per 1.73 m² surface area in adults. This means that, each day, ultrafiltration of 170–180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large

Figure 12.2 (a) Principal parts of the nephron. The point where the distal tubule is in close proximity to its own glomerulus is called the juxtaglomerular apparatus. This contains the macula densa.

(b) The countercurrent system. (i) *Vasa recta*: these vessels descend from the cortex into the medulla and then turn back towards the cortex. (ii) *Cortical nephron*: these have short descending limbs extending into the outer medulla. (iii) *Juxtamedullary nephron*: the descending limb dips deeply into the hypertonic inner medulla. Numbers indicate approximate osmolalities.

volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to ingest huge amounts of water and electrolytes to stay in balance. This is avoided by the selective reabsorption of water, essential electrolytes and other blood constituents, such as glucose and amino acids, from the filtrate in transit along the nephron. Thus, 60–80% of filtered water and sodium are reabsorbed in the proximal tubule along with virtually all the potassium, bicarbonate, glucose and amino acids (Fig. 12.2b). Additional water and sodium chloride are reabsorbed more distally, and fine tuning of salt and water balance is achieved in the distal tubules and collecting ducts under the influence of aldosterone and antidiuretic hormone (ADH). The final urine volume is thus 1–2 L daily. Calcium, phosphate and magnesium are also selectively reabsorbed in proportion to the need to maintain a normal electrolyte composition of body fluids.

The urinary excretion of some compounds is more complicated. For example, potassium is freely filtered at the glomerulus, almost completely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts.

A clinical consequence of this is that the ability to eliminate unwanted potassium is less dependent on GFR than is the elimination of urea or creatinine. Other compounds filtered and reabsorbed or secreted to a variable extent include urate, many organic acids and many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on the GFR; penicillin and cefradine are examples of drugs secreted by the tubules.

Urine concentration and the countercurrent system

Urine is concentrated by a complex interaction between the loops of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and the collecting ducts (see p. 640). The proposed mechanism of urine concentration is termed 'the countercurrent mechanism'. The countercurrent hypothesis states that: 'a small difference in osmotic concentration at any point between fluid flowing in opposite directions in two parallel tubes connected in a hairpin manner is multiplied many times along the length of the tubes'. Tubular fluid moves from the renal cortex towards the papillary tip of the medulla via the proximal straight tubule and the thin descending limb of the loop of Henle, which is permeable to water and impermeable to sodium. The tubule then loops back towards the cortex so that the direction of the fluid movement is reversed in the ascending limb, which is impermeable to water but permeable to sodium. This results in a large osmolar concentration difference between the corticomedullary junction and the hairpin loop at the tip of the papilla, and hence countercurrent multiplication. There is an analogy with heat exchangers.

Since the urine that emerges from the proximal tubule is iso-osmotic, the first nephron segment actually involved in urinary concentration is the descending limb of Henle's loop. There are two types of descending limbs (Fig. 12.2b).

- **The short loops** originate in superficial and midcortical glomeruli, and turn in the outer medulla. Approximately 85% of nephrons have these.
- **The long loops**, which originate in the deep cortical and juxtamedullary glomeruli, comprise 15% of nephrons which penetrate the outer medulla up to the tip of the papilla.

Both the ascending limb in the outer and inner medulla and the first part of the distal tubule are impermeable to water and urea. Through the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter, the thick ascending limb actively transports sodium chloride, increasing the interstitial tonicity, resulting in tubular dilution with no net movement of water and urea on account of low permeability. The hypotonic fluid under ADH action undergoes osmotic equilibration with the interstitium in the late distal and the cortical and outer medullary collecting duct, resulting in water removal. Urea concentration in the tubular fluid rises on account of low urea permeability. At the inner medullary collecting duct, which is highly permeable to urea and water, especially in response to ADH, the urea enters the interstitium down its concentration gradient, preserving interstitial hypertonicity and generating high urea concentration in the interstitium.

The hypertonic interstitium pulls water from the descending limb of the loop of Henle, which is relatively impermeable to NaCl and urea. This makes the tubular fluid hypertonic with high NaCl concentration as it arrives at the bend of the loop of Henle. Urea plays a key role in the generation of medullary interstitial hypertonicity. The urea that is reabsorbed into the inner medullary stripe from the terminal inner medullary

collecting duct is carried out of this region by ascending vasa recta, which deposit urea into the adjacent descending limb of both short and long loops of Henle, thus recycling the urea to the inner medullary collecting tubule. This process is facilitated by the close anatomical relationship that the hairpin loop of Henle and the vasa recta share.

Glomerular filtration rate (GFR)

In health, the GFR remains remarkably constant owing to intrarenal regulatory mechanisms. In disease (e.g. a reduction in intrarenal blood flow, damage to or loss of glomeruli or obstruction to the free flow of ultrafiltrate along the tubule), the GFR will fall. The ability to eliminate waste material and to regulate the volume and composition of body fluid will decline. This will be manifest as a rise in the plasma urea or creatinine and as a reduction in measured GFR.

The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50–60% in the GFR. Thereafter, the level of urea depends both on the GFR and its production rate (Table 12.1). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and, in general, measurement of serum creatinine is a good way to monitor further deterioration in the GFR.

It must be re-emphasized that a normal serum urea or creatinine is not synonymous with a normal GFR.

Measurement of the glomerular filtration rate

Measurement of the GFR is necessary to define the exact level of renal function. It is essential when the serum (plasma) urea or creatinine is within the normal range. The most widely used measurement is the creatinine clearance (Fig. 12.4).

Creatinine clearance is dependent on the fact that daily production of creatinine (principally from muscle cells) is remarkably constant and little affected by protein intake. Serum creatinine and urinary output thus vary very little throughout the day.

Creatinine excretion is, however, by both glomerular filtration and tubular secretion, although at normal serum levels the latter is relatively small.

Table 12.1 Factors influencing serum urea levels

Production	Elimination
Increased by High-protein diet Increased catabolism Surgery Infection Trauma Corticosteroid therapy Tetracyclines Gastrointestinal bleeding Cancer Decreased by Low-protein diet Reduced catabolism, e.g. old age Liver failure	Increased by Elevated GFR, e.g. pregnancy Decreased by Glomerular disease Reduced renal blood flow Hypotension Dehydration Urinary obstruction Tubulointerstitial nephritis
GFR, glomerular filtration rate.	

Figure 12.4 Creatinine clearance vs serum creatinine. Note that the serum creatinine does not rise above the normal range until there is a reduction of 50–60% in the glomerular filtration rate (creatinine clearance).

With progressive renal failure, creatinine clearance may overestimate GFR but, in clinical practice, this is seldom significant.

Given these observations, creatinine clearance, is nevertheless a reasonably accurate measure of GFR – **normal or near normal renal function**. Urine is collected over 24 h for measurement of urinary creatinine. A single plasma level of creatinine is measured some time during the 24-hour period.

$$\text{Creatinine clearance} = U \times VP$$

where U = urine concentration of creatinine; V = rate of urine flow in mL/min; P = plasma concentration of creatinine. Normal ranges are 90–140 mL/min in men, 80–125 mL/min in women.

Calculated GFR. Measurement of true GFR is cumbersome, time-consuming and may be inaccurate if 24-hour urine collections are incomplete. Therefore, several formulae have been developed that allow a prediction of creatinine clearance or GFR from serum creatinine and demographics. The Cockcroft–Gault equation for creatinine clearance is shown in Box 12.1.

A prediction equation has been developed based on the data derived from the Modification of Diet in Renal Disease (MDRD) study in people with chronic kidney disease (CKD) (Box 12.1). This equation is based on age, sex, creatinine and ethnicity. A modification of MDRD equation is used by most chemical pathology laboratories to calculate eGFR but it is less reliable if actual GFR is >60 mL/min and can result in inappropriate referral to renal physicians.

A new equation, the CKD Epidemiology Collaboration (CKD-EPI) equation, uses the same four variables as the MDRD Study equation and is more accurate for estimating GFR, especially at higher GFRs. The improved accuracy is mainly due to a substantial decrease in systematic differences between mGFR and eGFR (bias). The CKD-EPI equation is more accurate than the MDRD study equation overall and across most subgroups. In contrast to the MDRD study

Box 12.1 Estimation of glomerular filtration rate (GFR)

Cockcroft–Gault equation

$$\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times (\text{constant})}{\text{Serum creatinine } [\mu\text{mol/L}]}$$

Constant = 1.23 for males and 1.04 for women.

Modification of diet in renal disease (MDRD) equation

Calculation of estimated GFR by four variables:

$$\text{Estimated GFR (mL/min/1.73 m}^2\text{)} = 186 \times (\text{S}_{\text{Cr}})^{-1.154} \times (\text{age})^{-0.203} \times \text{constant (0.742 if female)} \times (1.210 \text{ if black African})$$

To convert creatinine values in $\mu\text{mol/L}$ to mg/dL multiply by 0.0113.

CKD Epidemiology (CKD-EPI) Collaboration equation

Adapted from: MacGregor MS, Boag DE, Innes A. Chronic kidney disease. *Quarterly Journal of Medicine* 2006; 99:365–375.

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 141 \times \min(\text{serum creatinine}/\kappa, 1)^2 \times \max(\text{serum creatinine}/\kappa, 1)^{-1.209 \times 0.993 \text{Age} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]}}$$

where κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum or serum creatinine/ κ or 1, and max indicates the maximum of serum creatinine/ κ or 1.

equation, eGFR >60 mL/min/1.73 m² **can be** reported using the CKD-EPI equation.

All these equations have not, however, been fully validated across all ranges of renal impairment, weights or body mass index (BMI), or ethnic groups; this makes them unreliable in the monitoring of patients with acute or chronic kidney disease while being treated and some clinicians still rely on measured creatinine clearance. In clinical practice, eGFR is reliable enough.

Tubular function

The major function of the tubule is the selective reabsorption or excretion of water and various cations and anions to keep the volume and electrolyte composition of body fluid normal (see Ch. 13).

The active reabsorption from the glomerular filtrate of compounds such as glucose and amino acids also takes place. Within the normal range of blood concentrations these substances are completely reabsorbed by the proximal tubule. However, if blood levels are elevated above the normal range, the amount filtered (filtered load = GFR \times plasma concentration) may exceed the maximal absorptive capacity of the tubule and the compound ‘spills over’ into the urine. Examples of this occur with hyperglycaemia in diabetes mellitus or elevated plasma phenylalanine in phenylketonuria.

Conversely, inherited or acquired defects in tubular function may lead to incomplete absorption of a normal filtered load, with loss of the compound in the urine (a lowered ‘renal threshold’). This is seen in renal glycosuria, in which there is a genetically determined defect in tubular reabsorption of glucose. It is diagnosed by demonstrating glycosuria in the presence of normal blood glucose levels. Inherited or acquired defects in the tubular reabsorption of amino acids, phosphate, sodium, potassium and calcium also occur, either singly or in combination. Examples include cystinuria and Fanconi’s syndrome (see p. 1040 and Ch. 13). Tubular defects in the reabsorption of water result in nephrogenic

diabetes insipidus (p. 992). Under normal circumstances, antidiuretic hormone induces an increase in the permeability of water in the collecting ducts by attachment to receptors with subsequent activation of adenylyl cyclase. This then activates a protein kinase, which induces preformed cytoplasmic vesicles containing water channels (termed 'aquaporins') to move to and insert into the tubular luminal membrane. This allows water entry into tubular cells down a favourable osmotic gradient. Water then crosses the basolateral membrane and enters the bloodstream. When the effect of ADH wears off, water channels return to the cell cytoplasm (see Fig. 13.5).

Acid-base balance

Tubular function is also critical to the control of acid-base balance. Thus, filtered bicarbonate is largely reabsorbed and hydrogen ions are excreted mainly buffered by phosphate (see p. 698).

Investigation of tubular function in clinical practice

Various tubular mechanisms could theoretically be investigated, but, in clinical practice, tests of tubular function are required less often than glomerular function.

Twenty-four-hour sodium output may be helpful in determining whether a patient is complying with a low-salt diet and in the management of salt-losing nephropathy. Tests of proximal tubular function may be required in the diagnosis of Fanconi's syndrome or isolated proximal tubular defects (e.g. urate clearance). Bicarbonate, glucose, phosphate and amino acid are all reabsorbed in the proximal tubule. Their presence in the urine is abnormal, and though formal methods of measuring maximal reabsorption are available, they are seldom necessary.

Retinol-binding protein and β_2 -microglobulin are normally reabsorbed by the proximal tubule, and their urinary excretion is nonspecifically increased by diseases of the proximal tubule.

Two tests of distal tubular function are commonly applied in clinical practice:

- **Measurement of urinary concentrating capacity** in response to water deprivation, and
- **Measurement of urinary acidification.**

These tests are dealt with on page 993 and page 665.

Protein and polypeptide metabolism

The kidney is a major site for the catabolism of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, parathyroid hormone (PTH) and calcitonin, by endocytosis carried out by the megalin-cubilin complex in the brush border of proximal tubular cells. In chronic kidney disease the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of patients with diabetes as their renal function declines.

Drug and toxicant elimination

A substantial fraction of prescription drugs are handled and eliminated by the kidney. Many of these medications (e.g. penicillins, cephalosporins, diuretics, NSAIDs, antivirals and methotrexate) circulate in the plasma as small organic anions. These organic anions, which are often bound to albumin, are actively eliminated by the proximal tubule of the nephron by an organic anion transporter (OAT) system. The OAT system

translocates drugs as well as endogenous substances and toxins.

Endocrine function

Renin-angiotensin system

Juxtaglomerular apparatus

The juxtaglomerular apparatus is made up of specialized arteriolar smooth muscle cells that are sited on the afferent glomerular arteriole as it enters the glomerulus. These cells synthesize prorenin, which is cleaved into the active proteolytic enzyme renin. Active renin is then stored in and released from secretory granules. Prorenin is also released in the circulation and comprises 50–90% of circulating renin, but its physiological role remains unclear as it cannot be converted into active renin in the systemic circulation. In the blood, renin converts angiotensinogen, an α_2 globulin of hepatic origin, to angiotensin I. Renin release is controlled by:

- Pressure changes in the afferent arteriole
- Sympathetic tone
- Chloride and osmotic concentration in the distal tubule via the macula densa (Fig. 12.2a)
- Local prostaglandin and nitric oxide release.

The renin-angiotensin-aldosterone system is illustrated in Figure 12.5.

Figure 12.5 The renin-angiotensin-aldosterone system. ACE inhibitors and angiotensin II antagonists can inhibit this system. ACE, angiotensin-converting enzyme.

Angiotensin I is inactive but is further cleaved by angiotensin-converting enzyme (ACE; present in lung and vascular endothelium) into the active peptide, *angiotensin II*, which has two major actions (mediated by two types of receptor, AT₁ and AT₂). The AT₁ subtype which is found in the heart, blood vessels, kidney, adrenal cortex, lung and brain mediates the vasoconstrictor effect. AT₂ is probably involved in vascular growth. Angiotensin II:

- causes rapid, powerful vasoconstriction
- stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days), leading to sodium and water retention.

Both of these actions will tend to reverse the hypovolaemia or hypotension that is usually responsible for the stimulation of renin release. Angiotensin II promotes renal NaCl and water absorption by direct stimulation of Na⁺ reabsorption in the early proximal tubule and by increased adrenal aldosterone secretion which enhances Na⁺ transport in the collecting duct.

In addition to influencing systemic haemodynamics, angiotensin II also regulates GFR. Although it constricts both afferent and efferent arterioles, vasoconstriction of efferent arterioles is three times greater than that of afferent, resulting in increase of glomerular capillary pressure and maintenance of GFR. In addition, angiotensin II constricts mesangial cells, reducing the filtration surface area, and sensitizes the afferent arteriole to the constricting signal of tubuloglomerular feedback (see p. 562). The net result is that angiotensin II has opposing effects on the regulation of GFR: (a) an increase in glomerular pressure and consequent rise in GFR; (b) reduction in renal blood flow and mesangial cell contraction, reducing filtration (see Fig. 12.48). In renal artery stenosis with resultant low perfusion pressure, angiotensin II maintains GFR. However, in cardiac failure and hypertension, GFR may be reduced by angiotensin II.

The renin-angiotensin system can be blocked at several points with renin inhibitors, angiotensin-converting enzyme inhibitors (ACEi) and angiotensin II receptor antagonists (A-IIRA). These are useful agents in treatment of hypertension and heart failure (see p. 782 and p. 719) but have differences in action: ACEis also block kinin production while A-IIIRAs are specific for the AT-II receptors.

Erythropoietin

Erythropoietin (see also p. 374) is the major stimulus for erythropoiesis. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium.

- Under *hypoxic* conditions both the α and β subunits of hypoxia inducible factor 2 (HIF-2) are expressed forming a heterodimer, causing erythropoietin gene transcription via the combined effects of hepatic nuclear factor 4 (HNF-4) and coactivator p300. Erythropoietin, once formed, binds to its receptors on erythroid precursor cells.
- Under *normal oxygen* conditions, only the HIF-2- β subunit is constitutively expressed. The α subunit undergoes proline hydroxylation in the presence of iron and oxygen by prolyl hydroxylase.
- The hydroxylated HIF-2- α subunit binds to von Hippel-Lindau protein and a ubiquitin ligase E3 complex is activated. This leads to ubiquitination (p. 31) and subsequent degradation of HIF-2- α via proteasomes so that no erythropoietin is transcribed. In normoxic conditions HIF-2- α also undergoes asparaginyl hydroxylation which prevents HIF complex from

recruiting coactivators. These hydroxylation steps have absolute requirement for molecular oxygen which forms the basis of oxygen sensing.

Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in people with polycystic renal disease, benign renal cysts or renal cell carcinoma. Recombinant human erythropoietin has been biosynthesized and is available for clinical use, particularly in people with chronic kidney disease (CKD) (see p. 623).

Vitamin D metabolism

Naturally occurring vitamin D (see also p. 622) (cholecalciferol) requires hydroxylation in the liver at position 25 and again by a 1 α -hydroxylase enzyme (mitochondrial cytochrome P450) mainly in the distal convoluted tubule, the cortical and inner medullary part of the collecting ducts and the papillary epithelia of the kidney to produce the metabolically active 1,25-dihydroxycholecalciferol (1,25-(OH)₂D₃). The 1 α -hydroxylase activity is increased by high plasma levels of parathyroid hormone (PTH), low phosphate and low 1,25-(OH)₂D₃. 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-(OH)₂D₃ (which therefore promotes its own inactivation).

Reduced 1 α -hydroxylase activity in diseased kidneys results in relative deficiency of 1,25-(OH)₂D₃. As a result, gastrointestinal calcium and to a lesser extent phosphate absorption is reduced and bone mineralization impaired. Receptors for 1,25-(OH)₂D₃ exist in the parathyroid glands, and reduced occupancy of the receptors by the vitamin alters the set-point for release of PTH in response to a given decrement in plasma calcium concentration. Gut calcium malabsorption, which induces hypocalcaemia, and relative lack of 1,25-(OH)₂D₃, contribute therefore to the hyperparathyroidism seen regularly in patients with CKD, even of modest degree.

Autocrine function

Endothelins

The endothelins ET-1, ET-2 and ET-3 are a family of similar potent vasoactive peptides that also influence cell proliferation and epithelial solute transport. They do not circulate but act locally. ETs are produced by most types of cells in the kidney. The vascular actions are mediated by two receptors, with ETA (specific for ET-1) mediating vasoconstriction and ETB (responsive to all ETs) causing vasodilatation. Endothelins inhibit sodium and water absorption by suppressing Na⁺/K⁺-ATPase and Na⁺/H⁺ antiporter activity in the proximal tubule and antagonizing the action of ADH and aldosterone in the collecting duct. Tubular transport actions are mediated by ETB. Endothelins, through vasoconstriction by ETA and salt and water retention via ETB receptors, cause hypertension. Endothelins, mainly through ETA receptors, can also alter cell proliferation and matrix accumulation by increasing tissue inhibitor of metalloproteinase (TIMP), cytokines, fibronectin and collagen. These peptides also stimulate the proliferation of a variety of renal cell types.

Prostaglandins

Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2 (see Fig. 15.30). COX-1 is highly

expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid to the same product, the bioactive but unstable prostanoid precursor, prostaglandin H_2 (PGH₂). PGH₂ is converted to:

- PGE₂ (formed by PDE₂ synthase in the collecting duct, responsible for natriuretic and diuretic effects)
- PGD₂ (undetermined significance, produced in proximal tubule)
- prostacyclin (PGI₂) (mainly synthesized in the interstitial and vascular compartment)
- thromboxane A₂ (vasoconstrictor, mainly synthesized in glomerulus).

They all act through G-coupled transmembrane receptors, maintaining renal blood flow and glomerular filtration rate in the face of reductions induced by vasoconstrictor stimuli such as angiotensin II, catecholamines and α -adrenergic stimulation. In the presence of renal underperfusion, inhibition of prostaglandin synthesis by non-steroidal anti-inflammatory drugs results in a further reduction in GFR, which is sometimes sufficiently severe as to cause acute kidney injury. Renal prostaglandins also have a natriuretic renal tubular effect and antagonize the action of antidiuretic hormone. Renal prostaglandins do not regulate salt and water excretion in normal subjects, but in some circumstances, such as CKD, prostaglandin-induced vasodilatation is involved in maintaining renal blood flow. Patients with CKD are thus vulnerable to further deterioration in renal function on exposure to non-steroidal anti-inflammatory drugs, as are elderly people, in many of whom renal function is compromised by renal vascular disease and/or the effects of ageing upon the kidney. Moreover, in conditions such as volume depletion, which are associated with high renin release (facilitated by prostaglandins), inhibition of prostaglandin synthesis may lead to hyperkalaemia due to hyporeninaemic hypoaldosteronism (since angiotensin II is the main stimulus for aldosterone).

Natriuretic peptides

Natriuretic peptides play a significant role in cardiovascular and fluid homeostasis, but there is no evidence of primary defects in their secretion causing disease.

Atrial natriuretic factors/peptides (ANP)

Atrial natriuretic peptides (ANP), a family of varying length forms, are secreted from atrial granules in response to atrial stretch. They produce marked effects on the kidney, increasing sodium and water excretion and glomerular filtration rate. ANP is also a direct vasodilator, lowering BP; it reduces renin release and aldosterone secretion and consequently inhibits angiotensin II synthesis.

Brain natriuretic peptide (BNP)

Brain natriuretic peptide (BNP) is found in the ventricle as well as the brain and has sequence homology with ANP. Normally its circulating level is 25% less than for ANP but may exceed it in congestive cardiac failure (p. 716).

Nitric oxide and the kidney

Nitric oxide (see Fig. 16.18), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS; p. 879). The most recognized cellular target of nitric oxide is soluble guanylate cyclase. The stimulation of this enzyme enhances the synthesis of cyclic GMP from GTP. All three isoforms are expressed in the kidney with eNOS in the

vascular compartment, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide mediates the following physiological actions in the kidney:

- Regulation of renal haemodynamics
- Natriuresis by inhibiting Na⁺/K⁺-ATPase and Na⁺/H⁺ antiporter and antagonizing ADH
- Modulation of tubuloglomerular feedback so that the composition of tubular fluid delivered to the macula densa changes the filtration rate of the associated glomerulus.

INVESTIGATIONS**Examination of the urine****Appearance**

This is of little value in the differential diagnosis of renal disease except in the diagnosis of haematuria. Overt 'bloody' urine is usually unmistakable but should be checked using dipsticks (Stix testing).

Volume

In health, the volume of urine passed is primarily determined by diet and fluid intake. In temperate climates it lies within the range 800–2500 mL per 24 h. The minimum amount passed to stay in fluid balance is determined by the amount of solute – mainly urea and electrolytes – being excreted and the maximum concentrating power of the kidneys would be approximately 650 mL.

In diseases such as CKD or diabetes insipidus, impairment of concentrating ability requires increased volumes of urine to be passed, given the same daily solute output. An increased solute output, such as in glycosuria or increased protein catabolism following surgery, also requires increased urine volumes.

Specific gravity and osmolality

Urine specific gravity is a measure of the weight of dissolved particles in urine, whereas urine osmolality reflects the number of such particles. Usually the relationship between the two is close. Measurement of urine specific gravity or osmolality is required only in the differential diagnosis of oliguric renal failure or the investigation of polyuria or inappropriate ADH secretion. Specific gravity is usually fixed at 1.010 in CKD or acute tubular necrosis as compared to pre-renal acute kidney injury and inappropriate ADH secretion where specific gravity is very high – close to 1.025.

Urinary pH

Measurement of urinary pH is unnecessary except in the investigation and treatment of renal tubular acidosis (see p. 664).

Chemical (Stix) testing

Routine Stix testing of urine for blood, protein and sugar is obligatory in all patients suspected of having renal disease.

Blood

Haematuria may be overt, with bloody urine, or microscopic and found only on chemical testing. A positive Stix test must always be followed by microscopy of fresh urine (with the exception of menstruating women) to confirm the presence of red cells or red-cell casts and so exclude the relatively rare conditions of haemoglobinuria or myoglobinuria. Bleeding may come from any site within the urinary tract (Fig. 12.6):

Figure 12.6 Sites and causes of bleeding from the urinary tract.

- **Overt bleeding from the urethra** is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- **Blood diffusely present** throughout the urine comes from the bladder or above.
- **Blood only at the end of micturition** suggests bleeding from the prostate or bladder base.

Protein

Proteinuria is one of the most common signs of renal disease. Detection is primarily by Stix testing. Most reagent strips can detect protein if albuminuria exceeds 300 mg/day. They react primarily with albumin and are relatively insensitive to globulin and Bence Jones proteins.

If proteinuria is confirmed on repeated Stix testing, protein excretion in 24-hour urine collections should be measured. Healthy adults excrete up to 30 mg daily of albumin. Pyrexia, exercise and adoption of the upright posture (*postural proteinuria*) all increase urinary protein output but are benign.

Microalbuminuria

Normal individuals excrete less than 20 µg of albumin per minute (30 mg in 24 hours). Dipsticks, however, detect albumin only in a concentration above 200 µg (300 mg per 24 hours if urine volume is normal). An albumin excretion between these two levels – called *microalbuminuria* – is an early indicator of diabetic glomerular disease and systemic endothelial dysfunction and is a useful prognostic marker for future cardiovascular events.

Timed 24-hour urinary excretion rates provide the most precise measure of microalbuminuria. However, in clinical practice it is more convenient, practical and relatively accurate to test for microalbuminuria using either random or early morning urine samples in which albumin concentration is related to urinary creatinine concentration. Generally an albumin:creatinine ratio (ACR) of 2.5:20 corresponds to albuminuria of 30–300 mg daily respectively. Kits are available to test for microalbuminuria. The urinary total protein:creatinine ratio (PCR) is also used for monitoring patients with CKD of various etiologies in their clinical practice. It is relatively

cheap and identifies patients whose proteinuria is of tubular rather than glomerular origin. ACR or PCR levels independently predict all-cause and cardiovascular mortality in the general population in addition to better risk stratifications of patients with CKD for future renal outcomes.

Glucose

Renal glycosuria is uncommon, so that a positive test for glucose always requires exclusion of diabetes mellitus.

Bacteriuria

Dipstick tests for bacteriuria are based on the detection of *nitrite* produced from the reduction of urinary nitrate by bacteria and also for the detection of leucocyte esterase, an enzyme specific for neutrophils. Although each test on its own has limitations, a positive reaction with both tests has a high predictive value for urinary tract infection (p. 593).

Microscopy

Urine microscopy should be carried out in all patients suspected of having renal disease, on a 'clean' sample of mid-stream urine. The presence of numerous skin squames suggests a contaminated, poorly collected sample that cannot be properly interpreted.

If a clean sample of urine cannot be obtained, suprapubic aspiration is required in suspected urinary tract infections, particularly in children.

- **White blood cells.** The presence of ≥ 10 WBCs/mm³ in fresh unspun mid-stream urine samples is abnormal and indicates an inflammatory reaction within the urinary tract such as urinary tract infection (UTI), stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis and interstitial cystitis.
- **Red cells.** The presence of one or more red cells per cubic millimetre in unspun urine samples results in a positive Stix test for blood and is abnormal.
- **Casts** are cylindrical bodies, moulded in the shape of the distal tubular lumen, and may be hyaline, granular or cellular. Coarse granular casts occur with pathological proteinuria in glomerular and tubular disease. Red-cell casts – even if only single – always indicate renal disease. White cell casts may be seen in acute pyelonephritis. They may be confused with the tubular cell casts that occur in patients with acute tubular necrosis.
- **Bacteria,** see page 593. Always culture urine prior to starting antibiotic therapy for sensitivities. Stix testing for blood or protein is of no value in the diagnosis of a UTI as both can be absent in the urine of many people with bacteriuria.

Blood and quantitative tests

The use of serum urea, creatinine and GFR as measures of renal function is discussed on page 564. Other quantitative tests of disturbed renal function are described under the relevant disorders, as are diagnostic tests, e.g. ANCA, immunofluorescence and complement.

Imaging techniques

Plain X-ray

A plain radiograph of the abdomen is valuable to identify renal calcification or radiodense calculi in the kidney, renal pelvis, line of the ureters or bladder (Fig. 12.7).

Investigations

Red-cell cast. Note aggregation of red cells as a 'cast' of the tubule.

Figure 12.7 Calcification in the renal tract. Calculi can occur at any site.

Ultrasonography

Ultrasonography of the kidneys and bladder has the advantage over X-ray techniques of avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis it is the imaging method of choice for:

- Renal measurement and for renal biopsy or other interventional procedures
- Checking for pelvicalyceal dilatation as an indication of renal obstruction when chronic renal obstruction is suspected. (In suspected acute ureteric obstruction, unenhanced spiral CT is the method of choice.)
- Characterizing renal masses as cystic or solid
- Diagnosing polycystic kidney disease
- Detecting intrarenal and/or perinephric fluid (e.g. pus, blood)
- Demonstrating renal arterial perfusion or detecting renal vein thrombosis using Doppler. *Doppler ultrasonography (duplex)* has the advantage of being non-invasive and is based on the principle that, when incident sound waves are reflected from a moving structure, their frequency is shifted by an amount proportional to the velocity of the reflector (e.g. an RBC); this shift can be quantified and displayed as a spectral Doppler scan or colour overlay (colour Doppler). However, duplex imaging is limited by central obesity, bowel gas and certain body habitus characteristics. Moreover, it is technically demanding, highly operator dependent, and is not universally available. It is at best a screening initial investigation and always requires confirmation by more reliable imaging techniques (CTA/MRA see below) if renal stenosis is suspected
- Measurement of bladder wall thickness in a distended bladder and to check for bladder tumours and stones. A scan obtained after voiding allows bladder emptying to be assessed.

The disadvantages of using ultrasonography to assess the urinary tract are:

- It does not show detailed pelvicalyceal anatomy
- It does not fully visualize the normal adult ureter

- It may miss small renal calculi and does not detect the majority of ureteric calculi
- It is operator-dependent.

In people with suspected benign prostatic hypertrophy, examination of the bladder before and after voiding, with measurement of the prostate, and examination of the kidneys to check for pelvicalyceal dilatation suffice. If prostate cancer is suspected, more detailed ultrasound examination of the prostate with a transrectal transducer, usually with transrectal prostate biopsy, is necessary.

Computed tomography (CT)

Computed tomography is used as a first-line investigation in cases of *suspected ureteric colic*. Multislice detector CT has both improved image resolution and allows reconstruction of the imaging data in a variety of planes. CT is also used to:

- Characterize renal masses which are indeterminate at ultrasonography
- Stage renal tumours
- Detect 'lucent' calculi (low-density calculi which are lucent on plain films, e.g. uric acid stones, are well seen on CT)
- Evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (periaortitis) and other causes of ureteric obstruction
- Assess severe renal trauma
- Visualize the renal arteries and veins by CT angiography
- Stage bladder and prostate tumours (MRI is increasingly used instead to stage prostate cancer).

Disadvantages include radiation and contrast nephrotoxicity (p. 614).

The use of unenhanced CT in suspected ureteric colic permits diagnosis of causes of pain other than calculi more readily than does urography.

Magnetic resonance imaging (MRI)

MRI is used:

- To characterize renal masses as an alternative to CT
- To stage renal, prostate and bladder cancer
- To demonstrate the renal arteries by magnetic resonance *angiography* with gadolinium as contrast medium. In experienced hands its sensitivity and specificity approaches renal angiography.

Magnetic resonance urography is preferred over intravenous urography (IVU) in patients with chronic urolithiasis or intrinsic or extrinsic ureteric tumour, and in paediatric uro-radiology. Gadolinium is used as contrast medium and is less nephrotoxic than iodine-containing agents used in IVU. However, the Federal Drug Administration (FDA) advises not using gadolinium in patients with renal insufficiency because of development of nephrogenic systemic fibrosis (pp. 1220 and 598).

Excretion urography

Excretion urography (also known as IVU or intravenous pyelography, IVP) has largely been replaced by ultrasonography and CT scanning.

Antegrade pyelography

Antegrade pyelography (Fig. 12.8) involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and ureter to the level of obstruction. It is used when

Figure 12.8 Antegrade pyelography via percutaneous catheter (small arrow) of obstructed system. Percutaneous drainage catheter (large arrow) has been inserted.

ultrasonography has shown a dilated pelvicalyceal system in a patient with suspected obstruction. Antegrade pyelography is the preliminary to percutaneous placing of a drainage catheter or ureteric stent in the obstructed pelvicalyceal system (percutaneous nephrostomy).

Retrograde pyelography

Following cystoscopy, preferably under screening control, a catheter is either impacted in the ureteral orifice or passed a short distance up the ureter, and contrast medium is injected. Retrograde pyelography is mainly used to investigate lesions of the ureter and to define the lower level of ureteral obstruction shown on CT or ultrasound plus antegrade studies. It is invasive, commonly requires a general anaesthetic, and may result in the introduction of infection.

Micturating cystourethrography (MCU)

This involves catheterization and the instillation of contrast medium into the bladder. The catheter is then removed and the patient screened during voiding to check for vesicoureteric reflux and to study the urethra and bladder emptying. It is used in children with recurrent infection (see p. 592).

MCU is not an appropriate investigation in adults because vesicoureteric reflux tends to disappear by the time adulthood is reached. The presence or absence of vesicoureteric reflux may also be investigated by scintigraphy (see below).

Aortography or renal arteriography

Conventional or digital subtraction angiography (DSA) is used. The latter allows the use of smaller doses of contrast medium which can be injected via a central venous catheter (venous DSA) or via a fine transfemoral arterial catheter (arterial DSA). Angiography is mainly used to define extrarenal or intrarenal arterial disease. Magnetic resonance angiography and multislice CT angiography are used (Fig. 12.9).

Figure 12.9 Magnetic resonance angiogram of normal renal arteries.

Complications include cholesterol embolizations (p. 599) and contrast-induced kidney damage (contrast nephropathy).

Renal scintigraphy

Renal scintigraphy using a gamma camera is divided into:

- dynamic studies in which the function of the kidney is examined serially over a period of time, most often using a radiopharmaceutical excreted by glomerular filtration
- static studies involving imaging of tracer that is taken up and retained by the renal tubule.

Dynamic scintigraphy

The radiopharmaceutical technetium-labelled diethylenetriaminepenta-acetic acid, [^{99m}Tc]DTPA, is excreted by glomerular filtration. Dimercaptosuccinic acid labelled with technetium (^{99m}Tc -DMSA) is filtered by the glomerulus and then bound to proximal tubular cells. Mercaptoacetyltriglycine (MAG3) labelled with technetium (^{99m}Tc) is excreted by renal tubular secretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. This information allows examination of blood perfusion of the kidney, uptake of tracer as a result of glomerular filtration, transit of tracer through the kidney, and the outflow of tracer-containing urine from the collecting system.

Renal blood flow. Dynamic studies can be used to investigate people in whom renal artery stenosis is suspected as a cause for hypertension and patients with severe oliguria (post-traumatic, post-aortic surgery, or after a kidney transplant) to establish whether, and to what extent, there is renal perfusion. In patients with unilateral renal artery stenosis there is, typically, a slowed and reduced uptake of tracer with delay in reaching a peak. Studies carried out before and after administration of an ACE inhibitor may demonstrate a fall in uptake that is suggestive of functional arterial stenosis. Both false-positive and false-negative results occur, particularly in patients with CKD, and renal arteriography remains the 'gold standard' in the diagnosis of renal artery stenosis. In patients with total renal artery occlusion, no kidney uptake of tracers is observed.

Investigation of obstruction. Renal scintigraphy provides functional evidence of obstruction. After injection usually of [^{99m}Tc]MAG3 a rise in resistance to flow in the pelvis or ureter prolongs the parenchymal transit of tracer and there is usually a delay in emptying the pelvis. On whole-kidney renograms, the time-activity curve fails to fall after an initial peak, or continues to rise (Fig. 12.10).

When the possibility of obstruction is suspected, a dynamic renal scintigram is performed with diuresis. Furosemide (0.5 mg/kg, adult dose 40 mg) is given intravenously about 18–20 min into the study. Time-activity curves show an immediate fall after furosemide in the absence of obstruction

Figure 12.10 Dynamic scintigram. Note the progressive rise of the right kidney curve to a plateau (in contrast to the normal left kidney curve) owing to urinary tract obstruction on the right side.

but the retention of activity in the pelvis persists in the presence of obstruction. A decision as to whether conservative surgery or nephrectomy should be carried out in unilateral obstruction is facilitated by renographic assessment of the contribution of each kidney.

At the end of dynamic studies, bladder emptying may be investigated and any postmicturition residual urine measured.

Glomerular filtration rate. This is discussed on page 564.

Static scintigraphy

This is usually performed using [^{99m}Tc]DMSA (dimercaptosuccinic acid), which is taken up by tubular cells. Uptake is proportional to renal function.

Relative renal function. Function is normally evenly divided between the kidneys, with a range of 45–55%. Static studies are particularly useful in unilateral renal disease, where the relative uptake of the two kidneys can be calculated.

Kidney visualization. Normal kidneys show a uniform uptake with a smooth renal outline. Scars can be identified as photon-deficient 'bites'. Static scintigraphy is of considerable value in identifying ectopic kidneys or 'pseudotumours' of the kidneys (i.e. normally functioning renal tissue abnormally placed within the kidney).

Localization of infection. The use of citrate labelled with gallium-67 or isotopically labelled leucocytes that are taken up by inflammatory tissue may be of value in defining localized infection, such as renal abscesses or infection within a renal cyst.

Transcutaneous renal biopsy

(Practical Box 12.1)

Renal biopsy is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. Renal biopsy is helpful in the investigation of the nephritic and nephrotic syndromes, acute and CKD, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like in situ hybridization and polymerase

Practical Box 12.1

Transcutaneous renal biopsy

Before biopsy

1. A coagulation screen is performed. It must be normal.
2. The serum is grouped and saved for cross-matching.
3. The patient is given a full explanation of what is involved and consent obtained.

During biopsy

1. The patient lies prone with a hard pillow under the abdomen.
2. The kidney is localized by ultrasound.
3. Local anaesthetic is injected along the biopsy track.
4. The patient holds a breath when the biopsy is performed.

After biopsy

1. A pressure dressing is applied to the biopsy site and the patient rests in bed for 8–24 hours.
2. The fluid intake is maximized to prevent clot colic.
3. The pulse and blood pressure are checked regularly.
4. The patient is advised to avoid heavy lifting or gardening for 2 weeks.

Table 12.2 Complications of transcutaneous renal biopsy

Macroscopic haematuria – about 20%
Pain in the flank, sometimes referred to shoulder tip
Perirenal haematoma
Arteriovenous aneurysm formation – about 20%, almost always of no clinical significance
Profuse haematuria demanding blood transfusion – 1–3%
Profuse haematuria demanding occlusion of bleeding vessel at angiography or nephrectomy – approximately 1 in 400
Introduction of infection
The mortality rate is about 0.1%

chain reaction analysis are also widely used in renal biopsy specimens.

The complications of transcutaneous renal biopsy are shown in Table 12.2.

GLOMERULAR DISEASES

A glomerulus consists of a collection of capillaries which come from the afferent arteriole and are confined within the urinary space (Bowman's capsule); this is continuous with the proximal tubule. The capillaries are partially attached to mesangium, a continuation of the arteriolar wall consisting of mesangial cells and the matrix. The free wall of glomerular capillaries (across which filtration takes place) consists of basement membrane covered by visceral epithelial cells with individual foot processes and lined by endothelial cells (Fig. 12.11). The normal thickness of the basement membrane is about 250–300 nm. The spaces between foot processes, with diameters of 20–60 nm, are called filtration pores, by which filtered fluid reaches the urinary space. The endothelial cells on the luminal aspect of the basement membrane are fenestrated (diameter 70–100 nm). The basement membrane is arranged in three zones: lamina rara externa, lamina rara densa and lamina rara interna, and is composed of type IV collagen and negatively charged proteoglycans (heparan sulphate).

Filtration barrier (slit diaphragm) (Fig. 12.12)

The glomerular filtration barrier consists of the fenestrated endothelium, the glomerular basement membrane and the terminally differentiated visceral epithelial cells known as podocytes. Podocytes dictate the size-selective nature of the filtration barrier. They attach to the glomerular basement membrane by foot processes via adhesion molecules, e.g. $\alpha_3\beta_1$ and dystroglycans. Adjacent podocytes are joined laterally via their foot process by slit diaphragms which bridge across the filtration slits. The various proteins comprising the slit diaphragm include nephrin, CD2AP (CD2-associated protein), canonical TRPC6 (transient receptor potential channel 6), podocin, P-cadherin, α - and β -catenin, ZO-1 (zonula occludens-1). These co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also have signalling functions in order to maintain the normal function of podocytes. Abnormalities in any of these proteins result in the breakdown of the filtration barrier with consequent torrential leak of macromolecules.

Figure 12.11 Diagram showing a normal (left) and proteinuric (right) glomerulus. A capillary loop showing normal glomerular morphology on the left with an epithelial cell with pseudopodia (foot processes). In the proteinuric diagram (right) there is fusion of the foot processes characteristic of many diseases. BM, basement membrane; MC, mesangial cell; MM, mesangial matrix.

Podocyte changes

The podocyte structure (see above) is maintained by actin which supports the cytoskeleton (Fig. 12.12). A rearrangement of the fluid actin cytoskeleton leads to foot process effacement (flattening) with a leak of albumin while its reversal (and stabilization) decreases proteinuria.

The cytoskeleton can be altered by abnormalities of the above cytoskeletal proteins, e.g. alpha-actinin-4, which causes hereditary focal segmental glomerular sclerosis, injury to the slit diaphragm proteins, changes in the glomerular basement membrane or by direct injury to the podocytes by, e.g. viral infection, drugs, toxins or the local activation of the renin-angiotensin system.

Types of glomerular disease

Glomerular disease includes:

- **glomerulonephritis**, i.e. inflammation of the glomeruli and
- **glomerulopathies**, where there is no evidence of inflammation.

There is an overlap between these terms.

GLOMERULOPATHIES

Glomerulopathies are the third most common cause of end-stage kidney disease (ESKD) (after diabetes and hypertension) in Europe and the USA, accounting for some 10–15% of such patients.

Glomerulopathy (GN) is a general term for a group of disorders in which:

- there is primarily an immunologically mediated injury to glomeruli, although renal interstitial damage is a regular accompaniment
- the kidneys are involved symmetrically
- secondary mechanisms of glomerular injury come into play following an initial immune insult such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage
- renal lesions may be part of a generalized disease (e.g. systemic lupus erythematosus, SLE).

Figure 12.12 The glomerular filtration barrier. (a) Blood enters the glomerular capillaries and is filtered across the endothelium and the glomerular basement membrane (GBM) and through the filtration slits between podocyte foot processes to produce the primary urine filtrate. In healthy glomeruli, this barrier restricts the passage of macromolecules. The proteins which form the slit diaphragm (SD) are essential for the normal functioning of the filtration barrier. (b) Loss of these proteins, either genetically or acquired, leads to foot process effacement and breakdown of the barrier and leakage of albumin. (a, b Adapted from Quaggin S. 2007 Sizing up sialic acid in glomerular disease. *Journal of Clinical Investigation* 117:1480–1483.) (c) Electron micrograph of normal filtration barrier.

Pathogenesis

GN is considered to be an immunologically mediated disorder with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement) and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, neoplasia or drugs. More frequently the underlying antigenic target is unknown. Primary GN may occur in genetically susceptible individuals following an environmental insult. The genetic susceptibility is usually determined by major histocompatibility complex (HLA) genes (e.g. HLA-A1, B8, DR2, DR3). The environmental factors may be drugs (e.g. hydralazine), chemicals (e.g. gold, silica, hydrocarbons) or infectious agents. The known predisposing factors are discussed in more detail below. The physical evidence of immune reactions is indicated by the presence of circulating autoantibodies and/or abnormalities in serum complement and glomerular deposition of antibodies, immune complexes, complement and fibrin.

Pathological terms in glomerular disease

The most commonly used terms are:

- **Focal:** some, but not all, glomeruli show the lesion
- **Diffuse** (global): most of the glomeruli (>75%) contain the lesion
- **Segmental:** only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis)
- **Proliferative:** an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- **Membrane alterations:** capillary wall thickening due to deposition of immune deposits or alterations in basement membrane
- **Crescent formation:** epithelial cell proliferation with mononuclear cell infiltration in Bowman's space.

Classification of glomerulopathies

There is no complete correlation between the histopathological types of GN and the clinical features of disease. Glomerular diseases have been classified in numerous ways. Here they are organized and discussed as they relate to four major glomerular syndromes:

- **Nephrotic syndrome** – massive proteinuria (>3.5 g/day), hypoalbuminaemia, oedema, lipiduria and hyperlipidaemia.
- **Acute glomerulonephritis (acute nephritic syndrome)** – abrupt onset of glomerular haematuria (RBC casts or dysmorphic RBC), non-nephrotic range proteinuria, oedema, hypertension and transient renal impairment.
- **Rapidly progressive glomerulonephritis** – features of acute nephritis, focal necrosis with or without crescents and rapidly progressive renal failure over weeks.
- **Asymptomatic haematuria, proteinuria** or both.

Certain types of GN, particularly those that are a part of a systemic disease, can present as more than one syndrome, e.g. lupus nephritis, cryoglobulinaemia, and Henoch–Schönlein purpura. They are usually associated with the nephrotic syndrome and will be discussed below. Investigation of glomerular diseases is shown in Table 12.3.

Table 12.3 Investigation of glomerular diseases

Investigations	Positive findings
Urine microscopy	Red cells, red-cell casts
Urinary protein	Nephrotic or sub-nephrotic range proteinuria
Serum urea	May be elevated
Serum creatinine	May be elevated
Culture (throat swab, discharge from ear, swab from inflamed skin)	Nephritogenic organism (not always)
Antistreptolysin-O titre	Elevated in post-streptococcal nephritis
C3 and C4 levels	May be reduced
Antinuclear antibody	Present in significant titre in systemic lupus erythematosus
ANCA	Positive in some vasculitis
Anti-GBM	Positive in Goodpasture's syndrome
Cryoglobulins	Increased in cryoglobulinaemia
Creatinine clearance	Normal or reduced
Chest X-ray	Cardiomegaly, pulmonary oedema (not always)
Renal imaging	Usually normal
Renal biopsy	Any glomerulopathy

Nephrotic syndrome

Pathophysiology

Hypoalbuminaemia. Urinary protein loss of the order 3.5 g daily or more in an adult is required to cause hypoalbuminaemia. The normal dietary protein intake in the UK is around 70 g daily and the normal liver can synthesize albumin at a rate of 10–12 g daily. How then does a urinary protein loss of the order of 3.5 g daily result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed albumin in the proximal tubules during the nephrotic syndrome even though actual albumin synthesis rate is increased. However, in addition, dietary intake of protein increases albuminuria, so that the plasma albumin concentration tends to decrease during consumption of a high-protein diet. If the increase in urinary albumin excretion that follows dietary augmentation is prevented by administration of ACE inhibitors (ACEI), a high-protein diet causes an increase in plasma albumin concentration in the nephrotic syndrome. Therefore, to maximize serum albumin concentration in nephrotic patients, a reduction in urinary albumin excretion with an ACEI is always necessary.

Proteinuria. The mechanism of the proteinuria is complex. It occurs partly because structural damage to the glomerular basement membrane leads to an increase in the size and number of pores, allowing passage of more and larger molecules. Electrical charge is also involved in glomerular permeability. Fixed negatively charged components are present in the glomerular capillary wall, which repel negatively charged protein molecules. Reduction of this fixed charge occurs in glomerular disease and appears to be a key factor in the genesis of heavy proteinuria.

Hyperlipidaemia. The characteristic disorder is an increase in the low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and/or intermediate-density lipoprotein (IDL) fractions, but no change or decrease in HDL. This results in an increase in the LDL/HDL cholesterol ratio. Hyperlipidaemia is the consequence of increased synthesis of lipoproteins

(such as apolipoprotein B, C-III lipoprotein (a)), as a direct consequence of a low plasma albumin. There is also a reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL) in direct response to albuminuria.

Oedema in hypoalbuminaemia. See Chapter 13 (p. 643).

Management

General measures

- **Initial treatment** should be with dietary sodium restriction and a thiazide diuretic (e.g. bendroflumethiazide 5 mg daily). Unresponsive patients require furosemide 40–120 mg daily with the addition of amiloride (5 mg daily), with the serum potassium concentration monitored regularly. Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema, and parenteral administration is then required initially. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted in order to avoid postural hypotension.
- **Normal protein intake** is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria and can be harmful in the long term.
- **Albumin infusion** produces only a transient effect. It is only given to patients who are diuretic-resistant and those with oliguria and uraemia in the absence of severe glomerular damage, e.g. in minimal-change nephropathy. Albumin infusion is combined with diuretic therapy and diuresis often continues with diuretic treatment alone.
- **Hypercoagulable states** predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should therefore be avoided as thromboembolism is very common in the nephrotic syndrome. In the absence of any contraindication, long-term prophylactic anticoagulation is desirable. If renal vein thrombosis occurs, permanent anticoagulation is required.
- **Sepsis** is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, is the best approach.
- **Lipid abnormalities** are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor.
- **ACE inhibitors and/or angiotensin II receptor antagonists** (AIIRA) are used for their antiproteinuric properties in all types of GN. These groups of drugs reduce proteinuria by lowering glomerular capillary filtration pressure; the blood pressure and renal function should be monitored regularly.

Specific measures

The aim is to reverse the abnormal urinary protein leak. These measures are discussed in detail below.

Table 12.4 shows the glomerular lesions commonly associated with the nephrotic syndrome. These are divided into diseases with or without RBC casts (active or bland urine sediments). Each of these entities occurs as a primary renal lesion or as a secondary component of a systemic disease.

Table 12.4 Glomerulopathies associated with the nephrotic syndrome

Nephrotic syndrome with 'bland' urine sediments	
Primary glomerular disease	
Minimal-change glomerular lesion	
Congenital nephrotic syndrome	
Focal segmental glomerular sclerosis	
Membranous nephropathy	
Secondary glomerular disease	
Amyloidosis	
Diabetic nephropathy

Figure 12.13 Normal glomerulus on light microscopy in minimal change disease.

Nephrotic syndrome with 'bland' urine sediments

Minimal-change glomerular lesion (minimal-change nephropathy, minimal-change disease, MCD)

In this condition the glomeruli appear normal on light microscopy (Fig. 12.13). The only abnormality seen on electron microscopy is fusion of the foot processes of epithelial cells (podocytes) (Fig. 12.12b; p. 573). This is a nonspecific finding and is seen in many conditions associated with proteinuria, e.g. focal segmental glomerulosclerosis (FSGS). Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence.

However, an explanation for the proteinuria is that immature differentiating CD34 stem cells rather than mature T lymphocytes are responsible for the pathogenesis of minimal change nephropathy. Other factors that may have an effect on the podocytes include IL-13, the production of vascular endothelial growth factor (VEGF), or the upregulation of vascular angiopoietin-like-4 (ANGPTL4) secreted by the podocytes.

Many drugs have been implicated in MCD, e.g. NSAIDs, lithium, antibiotics (cephalosporins, rifampicin, ampicillin), bisphosphonates and sulfasalazine. Atopy is present in 30% of cases of MCD and allergic reactions can trigger the nephrotic syndrome. Infections, e.g. HCV, HIV and TB, are rarer causes.

Clinical features

Minimal-change nephropathy is most common in children, particularly males, accounting for the large majority of cases

of nephrotic syndrome (proteinuria is usually highly selective) in childhood. Oedema is present and in children this may be facial. The condition accounts for 20–25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to CKD (but see FSGS, below).

Management

High-dose corticosteroid therapy with prednisolone 60 mg/m² daily (up to a maximum of 80 mg/day) for a maximum of 4–6 weeks followed by 40 mg/m² every other day for a further 4–6 weeks corrects the urinary protein leak in more than 95% of children. Response rates in adults are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema.

In children, two-thirds subsequently relapse and further courses of corticosteroids are required. One-third of these children regularly relapse on steroid withdrawal, so that cyclophosphamide should be added after repeat induction with steroids. A course of cyclophosphamide 1.5–2.0 mg/kg daily is given for 8–12 weeks with concomitant prednisolone 7.5–15 mg/day. This increases the likelihood of long-term remission. Steroid unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include azoospermia.

In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.

An alternative to cyclophosphamide is ciclosporin 3–5 mg/kg per day, which is effective but must be continued long term to prevent relapse on stopping treatment. The anti-proteinuric effect of ciclosporin is normally attributed to its immunosuppressive action but it may result from the stabilization of the actin cytoskeleton in kidney podocytes. Ciclosporin inhibits the calcineurin-mediated dephosphorylation of synaptopodin (a regulator of actin cytoskeleton) and protects it from cathepsin L-mediated degradation. These results have shed new light on the role of calcineurin signaling in proteinuric kidney diseases. Excretory function and ciclosporin blood levels (recommended trough levels 80–150 ng/mL) must be monitored regularly, as ciclosporin is potentially nephrotoxic.

In corticosteroid-dependent children, the anthelmintic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is useful in maintenance of remission but its mode of action is unexplained.

Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin, that occurs with a frequency of 1 per 8200 live births in Finland. Its loss of function results in massive proteinuria shortly after birth; these patients usually have an enlarged placenta. This disorder can be diagnosed *in utero*; increased α -fetoprotein in amniotic fluid is a common feature. The microscopic features of the kidney are varied. Some glomeruli are small and infantile, whereas others are enlarged, more mature and have diffuse mesangial hypercellularity. Because of the massive proteinuria, some tubules develop microcysts and are dilated. On electron microscopy, complete effacement of the foot processes of visceral epithelial cells is observed. This condition is characterized by relentless progression to ESKD.

Other inherited nephrotic syndromes involve mutations in other genes that encode podocyte proteins such as podocin, α -actinin-4 and Wilms' tumour suppressor gene.

Focal segmental glomerulosclerosis (FSGS)**Clinical features**

This disease of unknown aetiology usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. People with nephrotic syndrome are often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, particularly in patients with aggressive renal disease.

Aetiology. A circulating permeability factor causes the increased protein leak; plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. The identity of the permeability factor remains unknown but recent findings suggest that cardiotrophin-like cytokine-1 and/or soluble urokinase receptor are likely candidates in FSGS. In addition upregulation of CD80 in podocytes has a major role in the co-stimulatory immune response pathway. Anti-CD80 antibodies, used in renal transplantation, are likely to be used in FSGS in the future.

Pathology

This glomerulopathy is defined primarily by its appearance on light microscopy. Segmental glomerulosclerosis is seen, which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of a minimal-change glomerular lesion. A pathogenetic link may exist between minimal-change nephropathy (p. 575) and focal glomerulosclerosis, as a proportion of cases classified as having the former condition develop progressive CKD, which is unusual. Immunofluorescence shows deposits of C3 and IgM in affected portions of the glomerulus. The other glomeruli are usually enlarged but may be of normal size. In some patients, mesangial hypercellularity is a feature. Focal tubular atrophy and interstitial fibrosis are invariably present. Electron microscopic findings mirror light microscopic features with capillary obliteration by hyaline deposits (mesangial matrix and basement membrane material) and lipids. The other glomeruli exhibit primarily foot process effacement, occasionally in a patchy distribution.

Five histological variants of FSGS exist:

- In **classic FSGS** (Fig. 12.14a) the involved glomeruli show sclerotic segments in any location of the glomerulus.
- The **glomerular tip lesion** is characterized by segmental sclerosis, at the tubular pole of all the affected glomeruli at a very early stage (tip FSGS) (Fig. 12.14b). Capillaries contain foam cells, and overlying visceral epithelial cells are enlarged and adherent to the most proximal portion of proximal tubules. These patients have a more favourable response to steroids and run a more benign course.
- In **collapsing FSGS** (Fig. 12.14c) the visceral cells are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. These features indicate a severe lesion, with a corresponding progressive clinical

Figure 12.14 Focal segmental glomerulosclerosis (FSGS).

 (b) Glomerular tip lesions showing segmental sclerosis (arrow) at pole of glomerulus.
 (c) Collapsing FSGS (arrow).
 (d) FSGS perihilar variant.
 (e) FSGS cellular variant.

course of the disease. Collapsing FSGS is commonly seen in young blacks with human immunodeficiency virus (HIV) infection or disease and is known as HIV-associated nephropathy (HIVAN) (see p. 93).

- The **perihilar variant** (Fig. 12.14d) consists of perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. It is frequently observed with secondary FGS due to processes associated with increased glomerular capillary pressure and declining renal mass.
- The **cellular variant** (Fig. 12.14e) is characterized by at least one glomerulus with segmental endocapillary hypercellularity that occludes the capillary lumen. Other glomeruli may exhibit findings consistent with classic FGS.

The tip and collapsing variants have to be excluded histologically to make a diagnosis of the cellular variant. Patients with this variant can have severe proteinuria.

Similar glomerular changes are seen as a *secondary phenomenon* when the number of functioning nephrons is reduced for any reasons (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy and scarring following renal vasculitis), leading to the hypothesis that FSGS results from overloading (glomerular hyperfiltration) of the remaining nephrons.

Secondary forms are also caused by mutations in specific podocyte genes. Some viruses, e.g. HIV type 1, erythrovirus B19, cytomegalovirus, Epstein-Barr virus and the simian virus 40, are associated with FSGS. Drugs such as heroin, all interferons, anabolic steroids, lithium sirolimus, pamidronate and calcineurin inhibitors, e.g. ciclosporin, can also cause FSGS.

The cause of the *primary form* is unknown but could be due to circulating permeability factors mentioned above.

Treatment

- **Prednisolone** 0.5–2 mg/kg per day is used in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common.
- **Ciclosporin** at doses to maintain serum trough levels at 150–300 ng/mL may be effective in reducing or stopping urinary protein excretion. Relapse after reducing or

stopping ciclosporin is very common so that long-term use is required.

- **Cyclophosphamide, chlorambucil or azathioprine** are used for second-line therapy in adults. In patients with FSGS with mesangial hypercellularity and tip lesion, cyclophosphamide 1–1.5 mg/kg per day with 60 mg of prednisolone for 3–6 months followed by prednisolone and azathioprine can be used as maintenance therapy.

About 50% of patients progress to ESKD within 10 years of diagnosis, particularly those who are resistant to therapy. The recurrence of this renal lesion following renal transplantation is very high with poor renal prognosis. Plasmapheresis or immunoabsorption has been the mainstay of treatment in patients with post-transplant recurrence but with modest success.

Membranous glomerulopathy

Clinical features

This condition occurs mainly in adults, predominantly in males. People present with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. As in all nephritides, hypertension and a greater degree of renal impairment are poor prognostic signs. In membranous GN almost half of the patients undergo spontaneous or therapy-related remission. However, eventually about 40% develop CKD, usually in association with persistent nephrotic range proteinuria. Younger people, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

Aetiopathogenesis

An identical glomerular histological picture is seen in the primary or idiopathic form (which comprises 75% of the cases) and also when membranous GN is secondary to drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril), autoimmune disease (e.g. SLE, thyroiditis), infectious disease (e.g. hepatitis B, hepatitis C, schistosomiasis, *Plasmodium malariae*), neoplasia (e.g. carcinoma of lung, colon, stomach, breast and lymphoma) and other causes (e.g. sarcoidosis, kidney transplantation, sickle cell disease). At all stages, immunofluorescence shows the presence of uniform

granular capillary wall deposits of IgG and complement C3. In the early stage the deposits are small and can be missed on light microscopy. Electron microscopy reveals small electron-dense deposits in the subepithelial aspects of the capillary walls. In the intermediate stage the deposits are encircled by basement membrane, which gives an appearance of spikes of basement membrane perpendicular to the basement membrane on silver staining. Late in the disease the deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 12.15).

An animal model (Heymann nephritis) in which the morphological appearances closely resemble the human condition can be induced in susceptible rats by immunization with renal autoantigens such as the brush border component of proximal tubular cells, megalin (gp330). However, the target autoantigen in humans can not be megalin as it is absent from human podocytes.

A majority of patients with idiopathic membranous nephropathy have been found to have IgG4 type autoantibodies against phospholipase receptor A2 (PLA2R), a glycoprotein protein constituent of normal glomeruli. PLA2R is present in normal human podocytes and in immune deposits in patients with idiopathic membranous nephropathy, indicating that PLA2R could be a major autoantigen in this disease; it is linked to HLA-DQA1. Specific IgG4 autoantibodies to anti-aldose reductase (AR) and anti-manganese superoxide dismutase (SOD2) have also been found in the sera and glomeruli of patients with membranous nephropathy but not in other renal pathologies or normal kidney. This suggests

that AR and SOD2 could be additional renal autoantigens of human membranous nephropathy under certain clinical circumstances.

Treatment

There is no consensus on therapies for all cases but, in general, patients with moderate to heavy proteinuria are treated:

- Oral high-dose corticosteroids and azathioprine are not associated with any significant benefits.
- The alkylating agents, cyclophosphamide and chlorambucil, are both effective in the management of membranous GN but are reserved for patients with severe or prolonged nephrosis (i.e. proteinuria >6 g/day for >6 months), renal insufficiency and hypertension. There is a high likelihood of progression to ESKD.
- Chlorambucil (0.2 mg/kg per day in months 2, 4 and 6 alternating with oral prednisolone 0.4 mg/kg per day in months 1, 3 and 5) or cyclophosphamide (1.5–2.5 mg/kg per day for 6–12 months with 1 mg/kg per day of oral prednisolone on alternate days for the first 2 months) are equally effective.
- Ciclosporin and mycophenolate with oral steroids may become the agents of choice.
- Anti-CD20 antibodies (rituximab, which ablates B lymphocytes) have been shown to improve renal function, reduce proteinuria and increase the serum albumin; no significant adverse affects have been shown in the short term.

Amyloidosis (see p. 1042)

Amyloidosis is an acquired or inherited disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils causing progressive organ dysfunction and death.

Pathology

On light microscopy, eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Staining with Congo red renders these deposits pink and they show green birefringence under polarized light (Fig. 12.16). Immunofluorescence is unhelpful, but on electron microscopy the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of the cases as compared to almost 100% of patients with protein found in secondary amyloid (AA amyloid). Amyloid A (AA) amyloidosis, also referred to as secondary amyloidosis, is a rare but serious complication of chronic inflammatory diseases and chronic infections.

Figure 12.16 Amyloid. (a) Light microscopy of eosinophilic amyloid deposits (arrow). (b) Congo red stain under polarized light showing apple green birefringence.

Diagnosis and treatment

The *diagnosis* can often be made clinically when features of amyloidosis are present elsewhere. On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits *in vivo*, is used to detect the rate of regression or progression of amyloidosis over a period of time (p. 1043). Renal biopsy is necessary in all suspected cases of renal involvement.

Treatment. Treatments that reduce production of the amyloidogenic protein can improve organ function and survival in immunoglobulin-light-chain-related (AL) amyloidosis and hereditary transthyretin-associated (ATTR) amyloidosis (see p. 1042).

In AA amyloidosis, production of serum amyloid A can sometimes be decreased by treatment of the underlying inflammatory condition but cannot be completely suppressed. A new class of drug, eprodisate (see p. 1043), has shown modest success in patients with renal amyloidosis.

Renoprotective measures should be started (p. 622). The success of dialysis and kidney transplantation is dependent upon the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy

Diabetic renal disease is the leading cause of ESKD in the western world. People with type 1 and type 2 diabetes (see p. 1025) have equivalent rates of proteinuria, azotaemia, and ultimately ESKD. Both types of diabetes show strong similarities in their rate of renal functional deterioration, and onset of co-morbid complications.

Pathology

The kidneys enlarge initially and there is glomerular hyperfiltration (GFR >150 mL/min). The major early histological lesions seen are glomerular basement membrane thickening and mesangial expansion. Moreover, progressive depletion of podocytes (p. 573) from the filtration barrier due to either apoptosis or detachment and resulting podocyturia appears to be a very early ultrastructural change. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in the glomerular arterioles (Fig. 12.17). It has recently been shown that the mesangial expansion and the hyalinosis are partly due to amylin (beta islet specific amyloid protein) deposits. These later changes are associated with heavy proteinuria. The lesions seen in type 1 are also seen in type 2.

The Renal Pathology Society has developed a consensus classification combining type 1 and type 2 diabetic nephropathies (Table 12.5). This discriminates lesions by various degrees of severity for use in international clinical practice.

The pathophysiology is discussed on page 1025.

Figure 12.17 Diabetes mellitus. Advanced diabetic glomerulopathy and arteriolar sclerosis (arrow).

Table 12.5 Renal Pathology Society Classification of Type 1 and 2 diabetic nephropathy

Class	Name
I	Isolated glomerular basement membrane thickening (>395 nm in females, >430 nm in males). No evidence of mesangial expansion, mesangial matrix increase, or global glomerulosclerosis involving >50% of glomeruli
IIa	Mild mesangial expansion
IIb	Severe mesangial expansion (in a severe lesion >25% of the total mesangium contains areas of expansion larger than the mean area of a capillary lumen)
III	Nodular intercapillary glomerulosclerosis (≥1 Kimmelstiel–Wilson lesion(s)) and <50% global glomerulosclerosis
IV	Advanced diabetic glomerulosclerosis and >50% global glomerulosclerosis

Treatment

Lifestyle changes (cessation of smoking and increase in exercise), hypertension, poor metabolic regulation and hyperlipidaemia should be addressed in every diabetic. Microalbuminuria is a reason to start treatment with ACE inhibitors or an angiotensin II receptor antagonist (AIIIRA) in either type of diabetes, regardless of blood pressure elevation. Like other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. The timing of medical intervention during this silent phase (see Box 12.6) is renoprotective, as judged by slowed loss of glomerular filtration. Despite intensified metabolic control and antihypertension treatment in patients with diabetes, a substantial number still go on to develop ESKD. In a randomized controlled trial, the addition of paricalcitol (a selective activator of the vitamin D receptor) to treatment with ACE inhibitors reduced albuminuria (a surrogate marker of progressive renal disease) in patients with type 2 diabetes. Paricalcitol worked best in patients with a high sodium intake in their diet, who respond poorly to ACE inhibitor and ARB therapy.

Nephrotic syndrome with ‘active’ urine sediments (mixed nephrotic/nephritic)

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN)

This uncommon lesion has three subtypes with similar clinical presentations: the nephrotic syndrome, haematuria, hypertension and renal impairment. They also have similar microscopic findings although the pathogenesis may be different. Electron microscopy defines:

- **Type 1 MCGN.** There is mesangial cell proliferation, with mainly subendothelial immune deposition and apparent splitting of the capillary basement membrane, giving a ‘tram-line’ effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4 due to activation of the complement cascade by the classical pathway. It is often idiopathic but occurs with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 12.18a).
- **Type 2 MCGN.** There is mesangial cell proliferation with electron-dense, linear intramembranous deposits that usually stain for C3 only (Fig. 12.18b). This type may be

de Zeeuw D, Agarwal R, Amdahl M et al. Selective vitamin D receptor activation with paricalcitol for reduction of albuminuria in patients with type 2 diabetes (VITAL study): a randomised controlled trial. *Lancet* 2010; 376:1543–1551.

Figure 12.18 Mesangiocapillary glomerulonephritis (MCGN). (a) Type 1 MCGN showing expanded mesangial matrix and mesangial cells, thickened capillary wall, large subendothelial deposits and formation of a new layer of basement membrane (tram-line effect). (b) Type 2 MCGN. This shows a variable glomerular appearance; very electron-dense material has replaced Bowman's capsule, tubular basement membrane and part of the capillary. There is some proliferation of mesangial cells. (After: Marsh FP. *Postgraduate Nephrology*. Oxford: Butterworth Heinemann; 1985.)

idiopathic or be associated with partial lipodystrophy (loss of subcutaneous fat on face and upper trunk). MCGN affects young adults. These patients have low C3 levels as in type 1 but this is due to the activation of the alternative pathway of the complement cascade; they also have autoantibodies to C3 convertase enzyme.

- **Type 3 MCGN** has features of both types 1 and 2. Complement activation appears to be via the final common pathway of the cascade.

Most patients eventually go on to develop ESKD over several years. Type 2 MCGN recurs in virtually 100% of renal transplant patients but recurrence is less common in type 1 (25%). However, recurrence does not interfere with long-term graft function.

Management

In idiopathic MCGN (*all age groups*) with normal renal function, non-nephrotic range proteinuria, no specific therapy is required. Follow-up every 4 months, with specific attention to blood pressure control, is required.

In *children* with the nephritic syndrome and/or impaired renal function, a trial of steroids is warranted (alternate-day prednisolone 40 mg/m² for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities is necessary.

In *adults* with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75–100 mg) daily or a combination of the two, should be given for 6–12 months. Again, if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of CKD is instituted (p. 622).

Mesangial proliferative GN (IgM nephropathy, C1q nephropathy)

In addition to minimal-change disease, there are two other disorders that usually present with heavy proteinuria with only minor changes on light microscopy.

IgM nephropathy is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits (IgM and complement) in the mesangial regions. People present with episodic or persistent haematuria with the nephrotic syndrome. Unlike minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50%. Between 10% and 30% develop progressive renal insufficiency with evidence of secondary FSGS

(p. 576) on repeat biopsy. A trial of cyclophosphamide with prednisolone is used with persistent nephrotic syndrome, particularly with a rising plasma creatinine concentration.

C1q nephropathy is very similar to IgM nephropathy in presenting features and microscopic appearance with the exception of C1q deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in people with negative serology (so-called 'seronegative lupus'). The distinguishing features are intense C1q staining and absence of tubuloreticular inclusions (attributable to high circulating α -interferon) on electron microscopy. Only some people are steroid dependent. Progression to CKD is, as in most glomerular diseases, most likely to occur in people with heavy proteinuria and renal insufficiency.

Systemic lupus erythematosus (lupus glomerulonephritis)

Overt renal disease occurs in at least one-third of SLE patients and, of these, 25% reach end-stage CKD within 10 years (see also p. 536). Histologically, almost all patients will have changes. Box 12.2 shows the progression of histological findings and the clinical picture from classes I to VI.

Serial renal biopsies show that in approximately 25% of patients, histological appearances change from one class to another during the interbiopsy interval. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA and the complement components C3, C1q and C4 on immunofluorescence.

Pathophysiology

SLE is now known to be an autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disorder (p. 535). Lupus nephritis typically has circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro) and complement activation which leads to reduced serum levels of C3, C4, and particularly C1q. C1q is the first component of the classical pathway of the complement cascade (see p. 51) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis. Anti-C1q antibodies may help in distinguishing a renal from a non-renal relapse. However, not all autoantibodies are pathogenic to the kidney. These nephrogenic antibodies have specific physicochemical characteristics and correlate well with the pattern of renal injury. DNA was thought to be the inciting autoantigen, but nucleosomes (structures comprising DNA and histone, generated during apoptosis) are the most likely

Box 12.2 Classification of lupus nephritis

Class I – Minimal mesangial lupus nephritis (LN), with immune deposits but normal on light microscopy. Asymptomatic.

Class II – Mesangial proliferative LN with mesangial hypercellularity and matrix expansion. Clinically, mild renal disease.

Class III – Focal LN (involving <50% of glomeruli) with subdivisions for active or chronic lesions. Subepithelial deposits seen. Clinically have haematuria and proteinuria; 10–20% of all LN.

Class IV – Diffuse LN (involving >50% of glomeruli) (Fig. 12.19) classified by the presence of segmental and global lesions as well as active and chronic lesions. Subendothelial deposits are present. Clinically, there is progression to the nephrotic syndrome, hypertension and renal insufficiency. Most common and most severe form of LN.

Class V – Membranous LN affects 10–20% of patients. Can occur in combination with III or IV. Good prognosis.

Class VI – Advanced sclerosing LN (≥90% globally sclerosed glomeruli without residual activity). This represents the advanced stages of the above, as well as healing. Immunosuppressive therapy is unlikely to help as it is 'inactive'. Progressive CKD.

Modified from International Society of Nephrology/Renal Pathological Society 2004.

Figure 12.19 Lupus nephritis type IV – a diffuse proliferative nephritis. There is proliferation of endothelial and mesangial cells.

autoantigen. Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated. Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate (within the glomerular basement membrane) inciting an inflammatory reaction and resulting in mesangial cell proliferation, mesangial matrix expansion and inflammatory leucocytes. Other pathogenic mechanisms include infarction of glomerular segments, thrombotic microangiopathy, vasculitis and glomerular sclerosis.

Although humoral responses are the main effector mediators of lupus nephritis, IgE autoantibodies, basophils and type 2 helper (Th2) cells are also involved. IgE-containing immune complexes trigger circulating basophils (thought to play a role in SLE) to home in on secondary lymphoid organs and express MHC class II. In secondary lymphoid organs, these activated basophils secrete interleukin-4 and thus promote Th2 cell differentiation. Th2 cells, in cooperation with basophils, enhance B-cell differentiation and survival, and the production of autoreactive antibodies. The immune complexes in which these auto reactive antibodies are present are subsequently deposited in glomeruli and most likely cause lupus nephritis.

The extraglomerular features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (anticardiolipin or lupus anticoagulant) (p. 538).

Management

Initial treatment depends on the clinical presentation but hypertension and oedema should always be treated. A definite histopathological diagnosis is required. *Type I* requires no treatment. *Type II* usually runs a benign course but some patients are treated with steroids.

- There have been a number of clinical trials with immunosuppressive agents have been trialled in *types III, IV and V* which are the most severe form of lupus nephritis. Outcomes of these types are affected by ethnicity, clinical characteristics, irreversible damage (on renal biopsy), initial response to treatment and the future frequency of renal flares.
- Steroids and high-dose intravenous cyclophosphamide or mycophenolate mofetil (MMF) are usually used for induction. In white populations, low-dose cyclophosphamide is a good alternative to high-dose cyclophosphamide as it is similarly effective and associated with less toxicity.
- Mycophenolate mofetil is as effective as high-dose intravenous cyclophosphamide in the induction phase with a similar safety profile but cyclophosphamide may be inferior to MMF in black and Hispanic people.
- Most patients respond to induction therapy. Remission is maintained with MMF (superior to azathioprine) and azathioprine, which is similar in effectiveness to ciclosporin in reducing the risk of relapse.
- B cell depletion with rituximab (anti-CD20) has been used in some patients with favourable results over the short term. However, controlled trials have not shown consistent results. It might be useful in severe, refractory lupus nephritis.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. The prognosis is better in patients with types I, II and V. Glomerulosclerosis (type VI) usually predicts end-stage renal disease (p. 581).

Cryoglobulinaemic renal disease

Cryoglobulins (CG) are immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

Type I: the cryoprecipitable immunoglobulin is a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.

Types II and III cryoglobulinaemias are mixed types. In each, a polyclonal IgG antigen is bound to an antiglobulin. In type II, the antiglobulin component, which is usually of the IgM or IgA class with rheumatoid factor activity, is monoclonal, while in type III it is polyclonal. Type II CGs account for 40–60% cases, while 40–50% of all CG cases are of type III.

Glomerular disease is more common in type II than in type III cryoglobulinaemia. In approximately 30% of these 'mixed' cryoglobulinaemias, no underlying or associated disease is found (essential cryoglobulinaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein–Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis and autoimmune rheumatic diseases (SLE, rheumatoid arthritis and Sjögren's syndrome). Glomerular pathological changes resemble MCGN (Fig. 12.18).

FURTHER READING

Ramos-Casals M et al. The cryoglobulinaemias. *Lancet* 2012; 379: 348–360.

Presentation is usually in the 4th or 5th decades of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud's phenomenon, evidence of systemic vasculitis, a polyneuropathy and hepatic involvement. The glomerular disease presents typically as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (commonest presentation) or features of CKD also occurs.

A reduction in concentration of early complement components with an elevation of later components, detection of CGs, monoclonal gammopathy, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder, is seen.

Spontaneous remission occurs in about one-third of cases and approximately one-third pursue an indolent course. Corticosteroid and/or immunosuppressive therapy with cyclophosphamide may be of benefit, but evaluation of treatment is difficult owing to the rarity of the disease and the occurrence of spontaneous remissions. Intensive plasma exchange or cryofiltration has been used in selected cases. Interferon with ribavirin reduces the viraemia in hepatitis C but does not influence the cryoglobulinaemia. Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising, reporting improvement in general manifestations as well as glomerulonephritis.

Henoch–Schönlein syndrome (purpura)

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and glomerulonephritis. Approximately 30–70% have clinical evidence of renal disease with haematuria and/or proteinuria. The renal disease is usually mild but the nephrotic syndrome and acute kidney injury can occur. The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In the more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no treatment of proven benefit; steroid therapy is ineffective. Treatment is usually supportive but with crescentic GN aggressive immunosuppression has been tried with variable outcome.

Idiopathic fibrillary glomerulopathy

In this rare condition, characteristic microfibrillary structures are seen in the mesangium and glomerular capillary wall on electron microscopy that are clearly different from those seen in amyloidosis; the fibrils are larger than those in amyloidosis (20–30 vs 10 nm diameter) and do not stain with Congo red. The median age at presentation is approximately 45 years (range 10–80 years). People present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and CKD (50%) that may progress rapidly: 40–50% of patients develop ESKD within 2–6 years.

No treatment is known to be of benefit, although isolated instances of an apparent response to corticosteroid and immunosuppressive therapy have been reported.

Immunotactoid glomerulopathy

In this disorder, microtubules which are much larger (30–40 nm diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying

cause in over 50% of cases. The clinical presentation and course are similar to fibrillary glomerulopathy. Complete or partial remission of the nephrotic syndrome can be achieved by various chemotherapeutic agents in over 80% of patients.

Fibronectin glomerulopathy

This is also a form of glomerulonephritis due to fibrillar deposits which, unlike amyloidosis but like fibrillary glomerulonephritis and immunotactoid glomerulopathy, is Congo red staining negative. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss of function mutation in uteroglobin.

Fibronectin glomerulopathy is extremely rare and was originally described only in Caucasians of European descent. An Asian family with this disease has since been reported. There are as yet no known cases in black or Hispanic people. It presents with varying degrees of proteinuria seen first between the ages of 20 and 40. This is followed by hypertension, microscopic haematuria, and slow progression to end-stage renal disease in most patients. Diagnosis is confirmed by renal biopsy which demonstrates enlarged glomeruli with minimal proliferation and massive Congo red negative fibrillary deposits in the capillary walls.

Treatment includes nonspecific measures such as adequate blood pressure control by blockade of the renin-angiotensin system. ESKD patients are treated with dialysis, and recurrence of disease following renal transplant has been noted.

Acute glomerulonephritis (acute nephritic syndrome) (Table 12.6)

This comprises:

- Haematuria (macroscopic or microscopic) – red-cell casts are typically seen on urine microscopy
- Proteinuria
- Hypertension
- Oedema (periorbital, leg or sacral)
- Temporarily oliguria and uraemia.

The histological pattern is characterized by cellular proliferation (mesangial and endothelial) and inflammatory cell infiltration (neutrophils, macrophages).

Post-streptococcal glomerulonephritis (PSGN)

The patient, usually a child, suffers a streptococcal infection 1–3 weeks before the onset of the acute nephritic syndrome.

Table 12.6 Diseases commonly associated with the acute nephritic syndrome

Post-streptococcal glomerulonephritis
Non-streptococcal post-infectious glomerulonephritis, e.g.
<i>Staphylococcus</i> , pneumococcus, <i>Legionella</i> , syphilis, mumps, varicella, hepatitis B and C, echovirus, Epstein-Barr virus, toxoplasmosis, malaria, schistosomiasis, trichinosis
Infective endocarditis
Shunt nephritis
Visceral abscess
Systemic lupus erythematosus (see p. 509)
Henoch–Schönlein syndrome (see p. 582)
Cryoglobulinaemia (see p. 581)

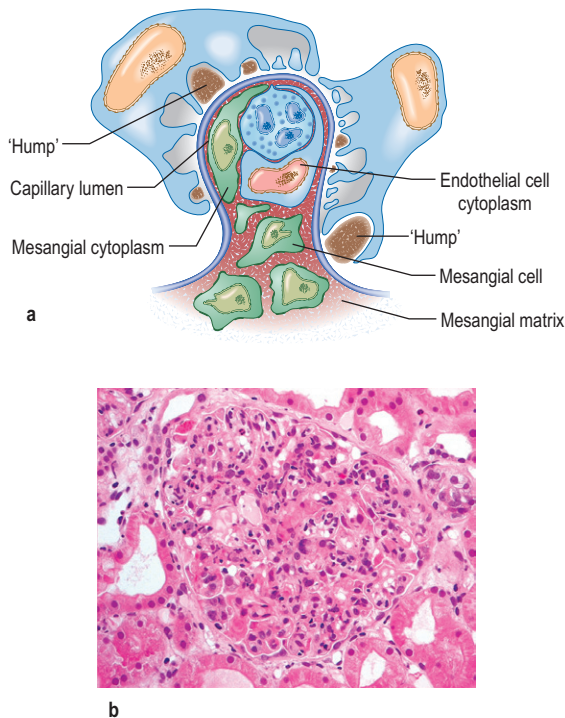

Figure 12.20 Post-streptococcal glomerulonephritis. (a) Diagram showing large aggregates of immune material (humps) in the extracapillary area. There is an increase in mesangial matrix and mesangial cells with occlusion of the capillary lumen by endothelial cell cytoplasm, leucocytes and mesangial cell cytoplasm. (b) Light microscopy showing acute inflammation of the glomerulus with neutrophils. (After: Marsh FP. *Postgraduate Nephrology*. Oxford: Butterworth Heinemann; 1985.)

Streptococcal throat infection, otitis media or cellulitis can all be responsible. The infecting organism is a Lancefield group A β -haemolytic streptococcus of a nephritogenic type. The latent interval between the infection and development of symptoms and signs of renal involvement reflects the time taken for immune complex formation and deposition and glomerular injury to occur. PSGN is now rare in developed countries. Renal biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally cellular crescents), with neutrophils and deposition of immunoglobulin (IgG) and complement (Fig. 12.20). Ultrastructural findings are those of electron-dense deposits, characteristically but not solely in the subepithelial aspects of the capillary walls. Endothelial cells often are swollen. Similar biopsy findings may be seen in *non-streptococcal post-infectious glomerulonephritis* (Table 12.6).

Management

The acute phase should be treated with antihypertensives, diuretics, salt restriction and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or CKD later in life. Therefore in older patients, an annual blood pressure check and measurement of serum creatinine are required. Evidence in support of long-term penicillin prophylaxis after the development of glomerulonephritis is lacking. In non-streptococcal post-infectious glomerulonephritis, prognosis is equally good if the underlying infection is eradicated.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis (usually i.v. drug users). It usually manifests itself as the acute nephritic syndrome. A similar presentation is in patients with infected ventriculoperitoneal shunt (*shunt nephritis*). Microscopic appearances resemble post-infectious GN, but lesions are usually focal and segmental. Crescentic GN with acute kidney injury has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases (embolic infarct of the kidney) usually results in a return of normal renal function.

Glomerulonephritis associated with visceral abscesses (mainly pulmonary)

Clinical and microscopic features are indistinguishable from post-infectious GN, but usually complement levels are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess result in complete recovery of renal function in approximately 50% of patients.

Asymptomatic urinary abnormalities

A variety of renal lesions may present as either isolated proteinuria or haematuria, alone or with proteinuria.

Isolated proteinuria without haematuria in asymptomatic patients is usually an incidental finding. It is usually in the sub-nephrotic range without an active urine sediment and there is normal renal function. Over 50% of these patients have postural proteinuria. The outcome of isolated proteinuria (postural or non-postural) is excellent in the majority of patients, with a gradual decline in proteinuria. Occasionally, it may be an early sign of a serious glomerular lesion such as membranous GN, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis. Moreover, mild proteinuria may accompany a febrile illness, congestive heart failure or infectious diseases with no clinical renal significance.

Haematuria with or without sub-nephrotic range proteinuria in an asymptomatic patient may lead to early discovery of potentially serious glomerular disease such as SLE, Henoch-Schönlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

IgA nephropathy (Fig. 12.21)

This disease has replaced post-streptococcal glomerulonephritis as the commonest form of glomerulonephritis worldwide. Demographic and family studies support the existence of a genetic contribution to the pathogenesis of IgA

Figure 12.21 IgA nephropathy. (a) Light microscopy. Showing mesangial cell proliferation (arrow) and increased matrix. (b) IgA deposits on immunoperoxidase staining.

nephropathy, but results from genetic association studies of candidate genes are inconsistent. In a genome-wide analysis study conducted in European patients showed a strong association on chromosome 6p in the region of the MHC/DQ and HLA-B loci. These results suggest that the HLA region contains the strongest common susceptibility alleles that predispose to IgA nephropathy in the European population.

Histology

There is a focal and segmental proliferative glomerulonephritis with mesangial deposits of polymeric IgA1. In some cases IgG, IgM and C3 are also seen in the glomerular mesangium.

A new Oxford histological classification for IgA nephropathy is shown in Table 12.7. The features have prognostic significance and it is recommended that they be taken into account for predicting outcome independent of the clinical features both at the time of presentation and during follow-up.

Pathogenesis

The disease may be a result of an exaggerated bone marrow and tonsillar IgA1 immune response to viral or other antigens and is associated with an abnormality in O-linked galactosylation in the hinge region of the IgA1 molecule. Functional abnormalities of two IgA receptors – CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells – are seen. IgA nephropathy is due to circulating immune complexes composed of a glycan-specific IgG and a galactose-deficient IgA1 antibody which deposit in the glomerular mesangium and induce the mesangio proliferative glomerulonephritis characteristic of IgA nephropathy. Removal of the complexes by bacterial proteases results in attenuation of IgA nephropathy. Available evidence suggests that glycan-specific autoantibodies rather than IgA1 itself may play a key role in the pathogenesis.

Up to 50% of patients exhibit elevated serum IgA (polyclonal) concentration. Superimposed crescent formation is frequent, particularly following macroscopic haematuria due to upper respiratory tract infection.

Several diseases are associated with IgA deposits, including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthritis, coeliac disease, mycosis fungoides and psoriasis.

Clinical presentation

IgA nephropathy tends to occur in children and young males. They present with asymptomatic microscopic haematuria or recurrent macroscopic haematuria sometimes following an upper respiratory or gastrointestinal viral infection. Proteinuria

occurs and 5% can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to 'lead-time bias' (p. 436), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of ESKD is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

Management

Patients with proteinuria over 1–3 g/day, mild glomerular changes only and preserved renal function should be treated with steroids. Steroids reduce proteinuria and stabilize renal function. Addition of azathioprine to steroids does not confer additional benefits. The combination of cyclophosphamide, dipyridamole and warfarin should not be used, nor should ciclosporin. In patients with progressive disease (eGFR <60 mL/min) fish oil or prednisolone with cyclophosphamide for 3 months followed by maintenance with prednisolone and azathioprine may be tried. A tonsillectomy can reduce proteinuria and haematuria in those patients with recurrent tonsillitis. All patients, with or without hypertension and proteinuria, should receive a combination of ACE inhibitor and angiotensin II receptor antagonist which enhances reduction of proteinuria and preservation of renal function. Mesangial IgA deposits are commonly found in the allografts of transplanted patients but loss of graft function as a result is uncommon.

Alport's syndrome

Alport's syndrome is a rare condition characterized by an hereditary nephritis with haematuria, proteinuria (<1–2 g/day), progressive kidney disease and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities such as bilateral anterior lenticonus and macular and perimacular retinal flecks. In about 85% of patients with Alport's syndrome there is X-linked inheritance of a mutation in the *COL4A5* gene encoding the *COL4A5* collagen chain. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. Patients with autosomal recessive or dominant modes of inheritance have also been described with mutations in *COL4A3* or *COL4A4* genes. In families with stromal cell tumours there is an additional mutation in the *COL4A6* gene.

Mutations present in Alport's syndrome that produce post-translational defects in $\alpha 3$, $\alpha 4$ and $\alpha 5$ chains result in

Table 12.7 Oxford histological classification for IgA nephropathy

Histological variable		Class
Mesangial hypercellularity	Average mesangial hypercellularity ^a >0.5 Average mesangial hypercellularity <0.5	M1 M0
Segmental glomerulosclerosis	Part of the glomerular tuft is involved in sclerosis No segmental glomerulosclerosis	S1 S0
Endocapillary hypercellularity	Hypercellularity present and results in lumina narrowing No hypercellularity	E1 E0
Tubular atrophy/interstitial fibrosis	Percentage of cortical area involved: >50 26–50 0–25	T2 T1 T0

^aMesangial hypercellularity is scored zero (0) for glomeruli with <4 mesangial cells per mesangial area; 1 for those with 4–5 cells; 2 for 6–7 cells; and 3 for ≥8 cells. Scores obtained for all glomeruli are then averaged.

incorrect assembly or folding of monomers; such defective monomers are rapidly degraded. These mutations arrest the normal developmental switch and cause the persistence of embryonic $\alpha 1$, $\alpha 1$ and $\alpha 2$ networks in glomerular basement membrane. These networks are more susceptible to endo-proteolysis and oxidative stress than the $\alpha 3$, $\alpha 4$ and $\alpha 5$ network. Over time, patients with Alport's syndrome probably become more sensitive to selective basement membrane proteolysis, which may explain why their glomerular membranes thicken unevenly, split and ultimately deteriorate.

The primary glomerular filtration barrier of the glomerular capillary consists of the basement membrane and the outer slit diaphragm formed between adjacent podocytes. Loss of slit function causes massive proteinuria (congenital nephrotic syndrome, p. 576) but deterioration of glomerular basement membrane produces only mild proteinuria. The mild proteinuria in Alport's syndrome is the result of glomerular sclerosis, rather than primary loss of slit pores. In pedigrees with a history of CKD, disease progresses from concomitant interstitial fibrosis, macrophage and lymphocyte infiltration secondary to tubular basement disruption and transdifferentiation of epithelial mesenchymal cells to fibroblasts. This fibrogenic response destroys renal architecture. The renal histology characteristically shows split basement membrane. In some patients with Alport's syndrome and carriers, thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport's and benign familial haematuria has become increasingly vague.

Management

The disease is progressive and accounts for some 5% of cases of ESKD in childhood or adolescence. Patients with mild CKD can be treated with ACE inhibitors to attenuate proteinuria. Exciting experimental evidence suggests that mesenchymal stem cells can transdifferentiate into podocytes and repair basement abnormalities and slow the rate of progression. Anti-GBM antibody does not adhere normally to the glomerular basement membrane of affected individuals but development of crescentic glomerulonephritis in the transplanted kidney due to anti-GBM alloantibody is a well-recognized complication.

Thin glomerular basement membrane disease

This condition is inherited as an autosomal dominant and typically presents with persistent microscopic glomerular haematuria (RBC casts or dysmorphic RBCs). The diagnosis is made by renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was underdiagnosed and is much commoner than previously believed. The prognosis for renal function is usually very good but some patients develop renal insufficiency over decades. The cause of renal impairment in this condition is not known but may be due to secondary FSGS or concomitant IgA nephropathy. Misdiagnosis occurs with Alport's syndrome which shares similar histological features. No treatment is of known benefit.

C3 glomerulonephritis/complement factor H-related protein 5 (CFHR5) nephropathy

This newly described familial renal disease mainly affects people of Cypriot origin and is an autosomal dominant trait. It is characterized by persistent microscopic hematuria, synpharyngitic macroscopic hematuria and progressive CKD culminating in ESKD.

Typically there is isolated glomerular accumulation of complement component 3 (C3) with variable degrees of glomerular inflammation. Patients have a heterozygous duplication in the CFHR5 gene; however, how this results in renal disease is not understood. Recurrence after renal transplantation suggests that CFHR5 protein derived from the new kidney cannot prevent the development of CFHR5 nephropathy.

CFHR5 nephropathy should be included in the differential diagnosis of familial haematuria and kidney disease, particularly if renal biopsy shows C3 deposition in the kidney. Even though IgA nephropathy with microscopic haematuria accompanied by macroscopic haematuria after an upper respiratory tract infection remains highly prevalent, CFHR5 nephropathy shares these features.

Standard CKD intervention is the only therapy which can be offered to these patients like in any other form of progressive kidney disease.

Rapidly progressive glomerulonephritis (RPGN)

RPGN is a syndrome with glomerular haematuria (RBC casts or dysmorphic RBCs), rapidly developing acute kidney failure over weeks to months and focal glomerular necrosis (Fig. 12.22) with or without glomerular crescent development on renal biopsy. The 'crescent' is an aggregate of macrophages and epithelial cells in Bowman's space (Fig. 12.22). RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g. SLE) or without immune deposits (pauci-immune, e.g. anti-PR3 and or anti-MPO-ANCA positive vasculitides). It can also develop as an idiopathic primary glomerular disease or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN and post-infective GN. The classification used here is based on the immunofluorescence information obtained from renal histology (Table 12.8), viz linear, granular and negative immunofluorescent patterns.

Anti-GBM glomerulonephritis (Fig. 12.23a)

Anti-GBM glomerulonephritis, characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15–20% of all cases of RPGN, although overall it accounts for less than 5% of all forms of glomerulonephritis. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture's syndrome with associated lung haemorrhage (p. 850). The remainder have a renal restricted anti-GBM RPGN, which is seen in patients over 50 years and affects both genders equally.

Anti-GBM antibodies (detected by ELISA) are present in serum and are directed against the *non-collagenous (NCI)* component of $\alpha 3$ (IV) collagen of basement membrane. This target antigen must be present as a component of the native

Figure 12.22 Rapidly progressive glomerulonephritis (RPGN). Arrows show 'crescents' with aggregates of macrophages and epithelial cells in Bowman's space. (a) Focal necrotizing glomerulonephritis. (b) Crescentic glomerulonephritis.

FURTHER READING

Gale DP, de Jorge EG, Cook HT et al. Identification of a mutation in complement factor H-related protein 5 in patients of Cypriot origin with glomerulonephritis. *Lancet* 2010; 376:794–801.

$\alpha 3$, $\alpha 4$, $\alpha 5$ (IV) network of selected basement membrane in order for pulmonary and renal disease to develop. Consequently, there are no known cases of anti-GBM glomerulonephritis in patients with Alport's syndrome (p. 584). However, the $\alpha 3$, $\alpha 4$, $\alpha 5$ (IV) network is also a target for anti-GBM alloantibodies in *Alport's syndrome* (see [this chapter](#)) *post-transplantation glomerulonephritis*, which occurs in 3–5% of patients with Alport's syndrome and results in allograft loss. Alport's post-transplantation nephritis is mediated by the deposition of alloantibodies to the $\alpha 3$ NC1 and $\alpha 5$ NC1 domains in response to the 'foreign' $\alpha 3$, $\alpha 4$, $\alpha 5$ (IV) collagen network that is absent in the patient's own kidneys with Alport's syndrome but present in the renal allograft. Alloantibodies in Alport's syndrome patients bind to epitopes in intact cross-linked $\alpha 345$ NC1 hexamers. In contrast, autoantibodies in Goodpasture's syndrome bind to native cross-linked $\alpha 345$ NC1 hexamers only if dissociated first to unmask hidden epitopes.

Anti-GBM RPGN is restricted by the major histocompatibility complex; HLA-DRB1*1501 and HLA-DRB1*1502 alleles increase susceptibility, whereas HLA-DR7 and HLA-DR1 are protective. The thymus expresses $\alpha 3$ (IV) NCI peptides that can eliminate autoreactive CD4⁺ helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory cells (Treg). Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in these autoreactive CD4⁺ cells producing anti-GBM antibodies. These

antibodies are very specific as shown by the fact that antibodies against $\alpha 1$, $\alpha 1$ and $\alpha 2$ NCI domains do not cause RPGN. Since the $\alpha 3$ (IV) NCI epitope is hidden within the $\alpha 3$, $\alpha 4$ and $\alpha 5$ (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.

The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane it activates complement and proteases and results in disruption of the filtration barrier and Bowman's capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by interleukin-12 and γ -interferon which are produced by resident and infiltrating inflammatory cells.

Management

This is based on counteracting the factors involved in the pathogenesis and employs:

- **Plasma exchange** to remove circulating antibodies
- **Steroids** to suppress inflammation from antibody already deposited in the tissue
- **Cyclophosphamide** to suppress further antibody synthesis.

The prognosis is directly related to the extent of glomerular damage (measured by percentage of crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600–700 $\mu\text{mol/L}$, renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/relapsing course. Furthermore, if left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in the convalescent patients. This is suggestive of re-establishment of peripheral tolerance which coincides with re-emergence of regulatory CD25⁺ cells in the peripheral blood; these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the 'single hit' nature of this condition.

ANCA-positive vasculitides (see also p. 544)

Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. *Wegener's granulomatosis*, *microscopic polyangiitis* and *Churg–Strauss syndrome* are described as small vessel vasculitides and are commonly associated with antineutrophil cytoplasm antibodies (ANCA).

Figure 12.24 Vasculitic rash.

These diseases share common pathology with focal necrotizing lesions, which affect many different vessels and organs; in the lungs, a capillaritis may cause lung haemorrhage; within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions (FNGN) may cause acute kidney injury (Fig. 12.22); in the dermis, a purpuric rash or vasculitic (Fig. 12.24) ulceration. Wegener's and Churg–Strauss syndrome may have additional granulomatous lesions.

Renal histology is regarded as a 'gold standard' for the diagnosis and prognostication of ANCA-associated GN. A consensus group proposed a new classification around four general categories of lesions:

- **Focal** ($\geq 50\%$ normal glomeruli that are not affected by the disease process)
- **Crescentic** ($\geq 50\%$ of glomeruli with cellular crescents)
- **Mixed** (a heterogeneous glomerular phenotype wherein no glomerular feature predominates)
- **Sclerotic** ($\geq 50\%$ of glomeruli with global sclerosis).

This system has been shown to have a prognostic value for 1- and 5-year renal outcomes. It is believed that it will aid in the prognostication of patients at the time of diagnosis and facilitate uniform reporting between centers. This classification at some point might also provide a means to guide therapy.

Pathogenesis

There are two forms of ANCA (p. 544), viz PR3-ANCA (cANCA) and MPO-ANCA (pANCA). If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%. Testing for antineutrophil cytoplasmic antibodies should be accompanied by appropriate tests of autoantibodies directed against DNA and the glomerular basement membrane antigen. The simultaneous occurrence of ANCA and anti-GMB antibody is well documented; such patients tend to follow the natural history of Goodpasture's syndrome. Variations in the ANCA titres have been used in the assessment of disease activity.

- **PR3-ANCA positivity** is found in the large majority ($>90\%$) of patients with active Wegener's granulomatosis and in up to 50% of patients with microscopic polyangiitis.
- **Anti-MPO positivity** is present in the majority of patients with idiopathic crescentic glomerulonephritis and in a variable number of cases of microscopic polyangiitis. There is some evidence to suggest that ANCA are pathogenic and not just markers of disease; for example, development of drug-induced ANCA is associated with vasculitic lesions in humans. Churg–Strauss syndrome may have either anti-MPO- or anti-PR3-ANCA.

- **Positivity for both types of ANCA** antibodies occurs in up to 10% of patients who have a variable clinical course but a worse renal outcome.
- **Drugs** (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitides associated with ANCA. Most patients reported with drug-induced ANCA-associated vasculitis have MPO-ANCA, often in very high titres. In addition to MPO-ANCA, most also have antibodies to elastase or to lactoferrin. A relatively small number have PR3-ANCA. Many cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgias/arthritis, and cutaneous vasculitis. However, the full range of clinical features associated with ANCA, including crescentic GN and lung haemorrhage, can also occur.

Both ANCA autoantigens are present in immature neutrophil granules. In contrast to the normally silenced state of these two genes in mature neutrophils of healthy subjects, PR3 and MPO are aberrantly expressed in mature neutrophils of patients with ANCA vasculitis due to unsilencing of both antigens because of an epigenetic modifications.

- **Autoimmunity.** It is unclear how and why autoimmunity causes the formation of ANCA antibodies. Patients with anti-PR3 also have autoantibodies to a peptide translated from the antisense DNA strand of PR-3 (complementary PR-3; cPR-3) or to a mimetic of this peptide. This suggests that autoimmunity can be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.
- **A recent study has shown** that infection by fimbriated bacteria (Gram-negative pathogens such as *Escherichia coli*, *Klebsiella pneumoniae* and *Proteus mirabilis*) can trigger, due to molecular mimicry, a cross-reactive autoimmunity to lysosomal membrane protein 2 (LAMP-2), a glycosylated membrane protein which is co-localized with PR3 and MPO in the intracellular vesicles of neutrophils.

There may be multiple factors that contribute to the initiation of an ANCA autoimmune response and the induction of injury by ANCA, such as genetic predisposition (α_1 -antitrypsin deficiency; Pi-Z allele) and environmental factors (e.g. silica exposure, viral infection, *Staph. aureus* infection) can result in high local or systemic pro-inflammatory cytokines such as tumour necrosis factor (TNF).

Treatment

The sooner treatment is instituted the more chance there is of recovery of renal function.

- **Corticosteroids** and **cyclophosphamide** are of benefit: high-dose oral prednisolone (maximum 80 mg/day reducing over time to 15 mg/day by 3 months) and cyclophosphamide (2 mg/kg per day, adjusted for age, renal function and prevailing WBC count). Intravenous pulse, rather than daily oral, cyclophosphamide is associated with an equivalent response with better side-effect profile but is associated with higher relapse rate. The best indicators of prognosis are pulmonary haemorrhage and severity of renal failure at presentation.
- Patients who present with **fulminant disease** need intensification of immunosuppression with adjuvant plasma exchanges ($7 \times 3-4$ L over 14 days) or intravenous pulse methyl prednisolone (1 g/day for 3 consecutive

days). Plasma exchange appeared to have better outcome than pulse methyl prednisolone in one study.

- Once remission has been achieved, azathioprine should be substituted for cyclophosphamide. In cases of intolerance to azathioprine or cyclophosphamide, mycophenolate or methotrexate has been tried with some success.
- Colonization of the upper respiratory tract with *Staph. aureus* increases the risk of relapse, and treatment with sulfamethoxazole/trimethoprim reduces the relapse rate.
- Relapse after complete cessation of immunosuppressive therapy has been observed relatively frequently, and therefore long-term, albeit relatively low-dose, immunosuppression is necessary.
- Intravenous immunoglobulin (anti-thymocyte globulin, ATG, directed against activated T lymphocytes causes lymphopenia), lymphocyte-depleting anti-CD52 (campath-1H) antibodies, and anti-TNF therapy have shown promise in the treatment of severe and drug-resistant cases as induction therapy. However, an anti-TNF agent, etanercept, has been ineffective as a sole agent for maintenance.
- Two studies have shown that rituximab is equally effective compared to cyclophosphamide for inducing remission in ANCA-associated vasculitides in the short term (6–12 months) with similar adverse event rates. Rituximab may be a therapeutic option in those patients who cannot tolerate cyclophosphamide, and patients whose disease is poorly controlled who relapse while on cyclophosphamide.
- Up to 25% of patients with PR3-ANCA harbour antibodies against human plasminogen and/or tissue plasminogen activator. Their presence has been correlated with venous thromboembolic events and fibrinoid necrotic glomerular lesions, suggesting functional interference with fibrinolysis. However, a formal role for anticoagulation in patients with ANCA-associated GN remains uncertain.

Other glomerular disorders

HIV-associated nephropathy (HIVAN)

A number of renal lesions have been described in association with HIV infection (see p. 177). These include glomerulonephritis of various histological types and the haemolytic uraemic syndrome. The most common (80–90%) histological abnormality is a focal glomerulosclerosis (FGS).

HIV-associated FGS

A characteristic ‘collapsed’ appearance of glomeruli is often seen on light microscopy similar to that seen in other causes of focal segmental glomerulosclerosis (see Fig. 12.14c). In HIVAN many visceral epithelial cells (podocytes) are enlarged, hyperplastic, coarsely vacuolated, contain protein absorption droplets and overlie capillaries with varying degrees of wrinkling and collapse of the walls. It is associated with loss of podocyte-specific markers such as Wilms’ tumour factor and synaptopodin due to HIV-1 infection of podocytes of patients with HIVAN. HIVAN has striking predilection; over 90% of patients are black. Clinically HIVAN presents with proteinuria in the nephrotic range, oedema and a ‘bland’ urine. Hypertension is unusual. If untreated, patients go on to CKD which can be rapid in progression.

IgA may be an integral feature of HIV-1 infection, as is IgA nephropathy. In this setting, HIV antigen may be a part of the glomerular immune complexes and circulating immune complexes.

Highly active antiretroviral therapy (HAART) may result in stabilization of renal function and prevention of progression to ESKD (efficacy 23%) and HIV-associated mortality in patients with ESKD. A cyclin-dependent kinase inhibitor, roscovitine, has been successfully used in the treatment of experimental HIVAN.

Fabry’s disease

This is the result of deficiency of the enzyme α -galactosidase with accumulation of sphingolipids in many cells. In the kidney, accumulation of sphingolipids especially affects podocytes, which on light microscopy appear enlarged and vacuolated. Ultrastructurally, these inclusion bodies appear as zebra or myeloid bodies representing sphingolipids. Similar appearances have been described in patients taking chloroquine, hydroxychloroquine and amantadine because these can cause hyperlipidosis. These structures can also be found in endothelial, mesangial, and arterial and arteriolar smooth muscle cells. The most common renal manifestation is proteinuria and progressive CKD.

Treatment (see p. 1034).

Sickle nephropathy

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection. The rare glomerular lesion is that of membranous GN or membranoproliferative GN with IgG deposits. No form of effective therapy is known.

Glomerulopathy associated with pre-eclampsia

The glomerular lesion of pre-eclampsia is characterized by marked endothelial swelling and obliteration of capillary lumina. Fibrinogen-fibrin deposits may be found in the mesangium. The renal lesion may not be reversible and 30% of patients have changes for ≥ 6 months. Patients who have had pre-eclampsia are more likely to develop hypertension in subsequent pregnancies. Severe proteinuria may occur during the course of pre-eclampsia and from time to time, produce features of nephrotic syndrome. Ordinarily, proteinuria disappears after delivery.

In severe cases, associated with cortical necrosis, there may be microangiopathic haemolytic anaemia. Vascular endothelial growth factor (VEGF) and placental growth factor (PLGF) play a key role in the development of the placenta.

Relative deficiency of either factor can theoretically cause implantation abnormalities normally seen in pre-eclampsia. A soluble fms-like tyrosine kinase (sFlt1) receptor also called VEGF-receptor, which is an antagonist of PLGF and specifically of VEGF, is upregulated in the placenta of patients with pre-eclampsia. High circulating levels of these receptors antagonize angiopoietic factors and cause endothelial dysfunction. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH

oxidase activity caused by generation of an angiotensin II receptor agonist antibody in some patients.

Paraneoplastic glomerulonephritis

A rare complication of malignancy, paraneoplastic glomerulonephritis is usually misdiagnosed as idiopathic glomerulonephritis. Such misdiagnosis can subject patients to potentially harmful, ineffective therapy.

The pathology of paraneoplastic glomerulonephritis varies depending on types of malignancy.

- **Thymoma or Hodgkin's lymphoma:** polarization of the immune response toward a T-helper-2 profile and possibly excessive production of interleukin-13 may lead to the development of minimal change disease or focal associated membranoproliferative glomerulonephritis and membranous nephropathy
- **B cell lymphoma and leukaemia** are related to the presence of monoclonal immunoglobulin, cryoglobulin, and possibly hepatitis C virus infection
- **Polycythaemia vera, essential thrombocythemia or primary myelofibrosis:** severe thrombocytosis may induce focal segmental glomerulosclerosis, possibly due to elevated levels of platelet derived growth factor
- **Myelodysplastic syndromes:** autoimmunity causes a variety of glomerulonephritides
- **Epithelial carcinoma:** the presence of glomerular inflammatory cells, and subepithelial immune IgG1- and IgG2-containing complexes are usually present and may aid in the diagnosis of paraneoplastic membranous nephropathy.

KIDNEY INVOLVEMENT IN OTHER DISEASES

Polyarteritis nodosa (PAN)

Classical PAN is a multisystem disorder (see also p. 543). Aneurysmal dilatation of medium-sized arteries may be seen on renal arteriography. The condition is more common in men and in the elderly and, typically, the patient is ANCA negative. Hypertension, polyneuropathy and features indicating ischaemic infarction of various organs including the kidney are presenting features. It may be associated with drug use and hepatitis B infection. This form of polyangiitis is associated with slowly progressive CKD, often accompanied by severe hypertension. Rapidly progressive kidney failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangiitis.

Systemic sclerosis (scleroderma)

Systemic sclerosis (scleroderma) is a chronic, multisystem disease characterized by fibrosis and vasculopathy of the skin and visceral organs. Of the patients, 10% develop scleroderma renal crisis, which is characterized by accelerated hypertension, rapidly progressive kidney failure and proteinuria.

Histopathological changes occur in the arcuate and interlobular arteries. Characteristically in the acute stage there are fibrin thrombi and areas of fibrinoid necrosis; these are followed by 'onion skin' hypertrophy of the arteries in the chronic stage. The treatment of choice is ACE inhibitors, which have led to remarkable improvement of outcomes in scleroderma renal crisis. Death is now rare, and <50% of patients progress to ESKD.

Figure 12.25 Typical haemolytic uraemic syndrome (HUS) renal lesion – light microscopy. Arrow shows microthrombi.

Haemolytic uraemic syndrome (HUS)

HUS is characterized by intravascular haemolysis with red-cell fragmentation (microangiopathic haemolysis), thrombocytopenia and acute kidney injury due to thrombosis in small arteries and arterioles (Fig. 12.25). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS.

Diarrhoea-associated HUS (D+HUS)

This often follows a febrile illness, particularly gastroenteritis and usually associated with *Escherichia coli*, notably strain O157. This strain of *E. coli* produces verocytotoxin (shiga toxin), which has an A unit and five B units. The A unit is pathogenic by inhibiting protein synthesis and initiating endothelial damage. The role of B units is to facilitate the entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. The toxins are transported to endothelial cells from the gut on neutrophils. Most patients with D+HUS recover renal function, but supportive care including maintenance of fluid and electrolyte balance, antihypertensive medication, nutritional support and dialysis is commonly required. Plasmapheresis is not beneficial but is usually tried as a last resort. About 5% die during the acute episode, 5% develop ESKD and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for the diarrhoea increase the risk of HUS and its complications.

Recently, an outbreak caused by shiga toxin-producing *Escherichia coli* O104:H4 (new strain) was reported in Germany and other European countries. In this outbreak, HUS cases were unusually high and associated with significant morbidity and mortality (see p. 121). Severe neurological complications were seen; immunoadsorption was successful in many cases.

Recurrent episodes of HUS have been described in the same individual, and familial forms of the disease (with both recessive and dominant inheritance) exist.

Non-diarrhoeal-induced form of HUS (D-HUS)

Also called atypical HUS (aHUS), this probably is a complement-driven illness due to a deficiency of complement factor H (CFH) or complement factor I (CFI). Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with D-HUS, a mutation has been traced to another complement regulatory protein, CD46 (previously known as membrane cofactor protein, MCP). This protein is highly expressed in the kidney and

FURTHER READING

Vikse BE, Irgens LM, Leivestad T et al. Preeclampsia and the risk of end-stage renal disease. *N Engl J Med* 2008; 359(8):800–809.

normally prevents glomerular C3 activation. A loss of function mutation in CD46 results in unopposed complement activation and development of HUS. Functional deficiency of these factors can be acquired due to autoantibody formation either as an isolated phenomenon or as part of a rheumatic autoimmune disease such as SLE. A loss of function mutation in thrombomodulin (a membrane-bound anticoagulant glycoprotein) has been identified as an alternative complement pathway. Rarely gain of function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3. CFB mutations, which lead to chronic alternative-pathway activation, occur in only 1–2% of patients with D-HUS. About 4–10% of patients have heterozygous mutations in C3, usually with low C3 levels. Most mutations reduce C3b binding to CFH and CD46, which severely impairs degradation of mutant C3b.

Treatment

Treatment is often very difficult because of severe hypertension and the possibility of frequent recurrences. The course of the disease is often indolent and progressive. Plasmapheresis or plasma infusion is still the only therapy used in the majority of patients. C5 activation is one of the critical steps in the activation of complement cascade. Eculizumab, a monoclonal humanized anti-C5 antibody, has shown success in patients with D-HUS either dependent or refractory to plasmapheresis therapy. Liver transplantation is potentially the only curative treatment in patients harbouring CFH and CFI mutations.

Sporadic cases of D-HUS

These can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Treatment is supportive with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmapheresis in these sporadic cases but it is tried, usually as a last resort.

Pneumococcus-associated HUS

This rare complication of *Streptococcus pneumoniae* infection was previously associated with a high morbidity and mortality. This organism produces an enzyme (possibly neuroaminidase) which can expose an antigen (Thomsen antigen) present on RBCs, platelets and glomeruli. Antibodies to the Thomsen antigen result in an antigen-antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of blood products (washed blood products) and avoiding plasma infusion or plasmapheresis.

Thrombotic thrombocytopenic purpura (TTP)

TTP (see p. 420) is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected.

Antiphospholipid syndrome (APS)

In antiphospholipid syndrome (APS, see p. 538), the binding of antiphospholipid antibodies (aPL) to beta 2 glycoprotein I (β 2GPI) induces endothelial cell-leukocyte adhesion and thrombus formation by the inhibition of eNOS. The inhibition of eNOS is caused by antibody recognition and dimerization of β 2GPI and impairment of eNOS phosphorylation.

The central feature of APS is recurrent thrombosis (both venous and arterial) and fetal loss in the presence of antiphospholipid antibodies. Such antibodies may be primary or secondary to infections (HIV, hepatitis C) or autoimmune disease (SLE). Some 50% have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but well-recognized presentation. In some cases, a lupus nephritis-like (usually membranous GN) lesion is seen. The only proven treatment for APS is warfarin with an INR of 3–4. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30–70%).

Multiple myeloma

Acute kidney injury (AKI) is relatively common in myeloma, occurring in 20–30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. It is often irreversible. The following types of renal lesions are associated with myeloma.

- **Light chain cast nephropathy** – intratubular deposition of light chains, particularly kappa chains facilitated by Tamm-Horsfall glycoprotein, which characteristically appear on renal histology as fractured casts with giant cell reaction (Fig. 12.26)
- **AL amyloidosis** – deposition of amyloid fibrils of light chains (Congo red positive)
- **Light chain deposition disease** – nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red negative)
- **Plasma cell infiltration** – often incidental finding at autopsy
- **Fanconi's syndrome** – tubular toxicity due to light chains
- **Hypercalcaemic nephropathy** – bone resorption causing hypercalcaemia
- **Hyperuricaemic nephropathy** – tumour lysis causing tubular crystallization of uric acid
- **Radiocontrast nephropathy** – interaction between light chains and radiocontrast.

Treatment of underlying myeloma is indicated (p. 471). If a patient with cast nephropathy and severe AKI remains dialysis-dependent, the prognosis is poor. Commencement of effective bortezomib based chemotherapy, which decreases light chain production, and a high cut-off haemodialysis has shown some promise in relapsed myeloma.

Figure 12.26 Cast nephropathy in a patient with multiple myeloma. Light microscopy picture showing characteristic fractured cast and giant cell reaction (arrows).

^aMore common in hospital practice.
^bMore common in young women (20–30%).

URINARY TRACT INFECTION

Urinary tract infection (UTI) is common in women, in whom it usually occurs in an anatomically normal urinary tract. Conversely, it is uncommon in men and children, and the urinary tract is often abnormal and requires investigation. The incidence of UTI is 50 000 per million persons per year and accounts for 1–2% of patients in primary care. Recurrent infection causes considerable morbidity; if complicated, it can cause severe renal disease including ESKD. It is also a common source of life-threatening Gram-negative septicaemia.

Aetiology and pathogenesis

Infection is most often due to bacteria from the patient's own bowel flora (Table 12.9). Transfer to the urinary tract is most often via the ascending transurethral route but may be via the bloodstream, the lymphatics or by direct extension (e.g. from a vesicocolic fistula).

Symptomatic infection is related to the virulence of the organisms, which compete with the innate host defence system. However, inflammation and injury are determined by the host response and not by the bacterium.

Virulence. Ability to adhere to epithelial cells determines the degree of virulence of the organism. For *E. coli*, these adhesive factors include flagellae (for motility), aerobactin (for iron acquisition in the iron-poor environment of the urinary tract), haemolysin (for pore forming) and above all, the presence of adhesins on the bacterial fimbriae and on the cell surface.

There are two types of *E. coli*: those with *type 1 fimbriae* (with adhesin known as FimH) associated with cystitis; and those with *type P fimbriae* (with adhesin known as PapG) commonly responsible for pyelonephritis. Bacterial adhesins are necessary for attachment of bacteria to the mucous membranes of the perineum and urothelium. There are several molecular forms of adhesins. The most studied is the PapG adhesin, which is located on the tip of P fimbriae. This lectin (one of the P blood group antigens) structure recognizes binding sites consisting of oligosaccharide sequences present on the mucosal surface.

Innate host defence. The following host defence mechanisms are necessary to prevent UTI:

- **Neutrophils** – adhesins activate receptors, e.g. Toll receptor 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor CXCR1 on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing. Defective IL-8 production or reduced expression of CXCR1 results in impaired function of neutrophils predisposing an individual to severe UTI.

- **Urine osmolality and pH** – urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.
- **Complement** – complement activation with IgA production by uroepithelium (acquired immunity) also plays a major role in defence against UTI.
- **Commensal organisms** – such as lactobacilli, corynebacteria, streptococci and bacteroides are part of the normal host defence. Eradication of these commensal organisms by spermicidal jelly or disruption by certain antibiotics results in overgrowth of *E. coli*.
- **Urine flow** – urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- **Uroepithelium** – mannoseylated proteins such as Tamm–Horsfall proteins (THP), which are present in the mucus and glycocalyx covering uroepithelium, have antibacterial properties. These proteins interfere with bacterial binding to uroepithelium. Disruption of this uroepithelium by trauma (e.g. sexual intercourse or catheterization) predisposes to UTI. Cranberry juice and blueberry juice contain a large-molecular-weight factor (proanthocyanidins) that prevents binding of *E. coli* to the uroepithelium (see p. 591).
- **Blood group antigens** – women who are non-secretors of ABH blood group antigens are three to four times more likely to have recurrent UTIs.

Natural history

UTI is commonly an isolated, rather than a repeated, event (Fig. 12.27).

Complicated versus uncomplicated infection

(Fig. 12.28)

It is necessary to distinguish between UTI occurring in patients with functionally normal urinary tracts and in those with abnormal tracts.

Functionally normal urinary tracts (with normal renal imaging). Here, persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI).

Abnormal urinary tracts. Tracts with stones, or associated diseases such as diabetes mellitus which themselves cause kidney damage, may be made worse with infection (complicated UTI). UTI, particularly with *Proteus*, may predispose to stone formation. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is a major cause of Gram-negative septicaemia.

Acute pyelonephritis

The combination of fever, loin pain with tenderness and significant bacteriuria usually implies infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically, there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.

Figure 12.27 The natural history of urinary tract infection.

FURTHER READING

Hooton TM. Uncomplicated urinary tract infection. *N Engl J Med* 2012; 366: 1028–1037.

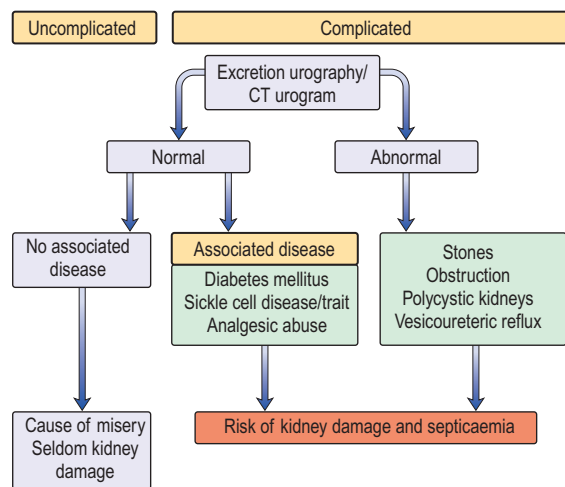

Figure 12.28 Complicated vs uncomplicated urinary tract infection.

Figure 12.29 CT scan showing a wedge-shaped area of renal cortical loss (arrow) following acute pyelonephritis.

Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the renal cortex (Fig. 12.29) and hence damage to renal function.

Reflux nephropathy

This was called chronic pyelonephritis or atrophic pyelonephritis, and it results from a combination of:

- vesicoureteric reflux, and
- infection acquired in infancy or early childhood.

Normally, the vesicoureteric junction acts as a one-way valve (Fig. 12.30), urine entering the bladder from above; the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children – possibly even *in utero* – this valve mechanism is incompetent, bladder voiding being associated with variable reflux of a jet of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage.

Typically, there is papillary damage, tubulointerstitial nephritis and cortical scarring in areas adjacent to ‘clubbed calyces’.

Figure 12.30 Findings in reflux nephropathy compared with normal.

Diagnosis is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral and affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base. Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux and therefore does not begin in adult life. Consequently, adult females with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

Chronic reflux nephropathy acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of ESKD in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral reimplantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that reimplantation surgery confers long-term benefit.

Reinfection versus relapsing infection

When UTI is recurrent, it is necessary to distinguish between relapse and reinfection.

Relapse is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment and implies failure to eradicate infection (Fig. 12.31) usually in conditions such as stones, scarred kidneys, polycystic disease or bacterial prostatitis.

Reinfection is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection, but is the result of reinvasion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to reinfection.

Symptoms and signs of UTI

The most typical symptoms of UTI are:

- Frequency of micturition by day and night
- Painful voiding (dysuria)
- Suprapubic pain and tenderness
- Haematuria
- Smelly urine.

These symptoms relate to bladder and urethral inflammation, commonly called ‘cystitis’, and suggest lower urinary

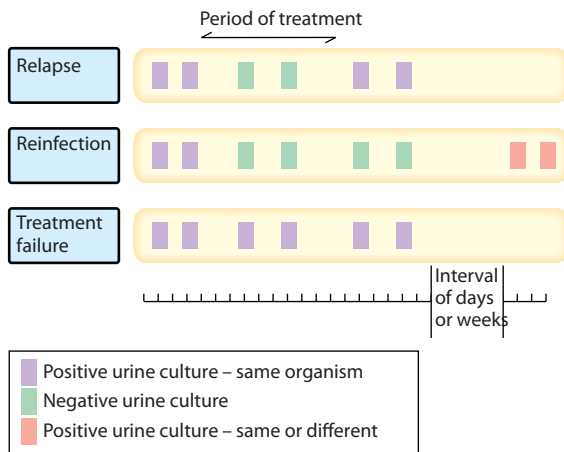

Figure 12.31 A comparison of reinfection, relapse and treatment failure in urinary tract infection.

Table 12.10 Criteria for diagnosis of bacteriuria

Symptomatic young women

$\geq 10^2$ coliform organisms/mL urine plus pyuria (>10 WCC/ mm^3)

or

$\geq 10^5$ any pathogenic organism/mL urine

or

any growth of pathogenic organisms in urine by suprapubic aspiration

Symptomatic men

$\geq 10^3$ pathogenic organisms/mL urine

Asymptomatic patients

$\geq 10^5$ pathogenic organisms/mL urine on two occasions

tract infection. Loin pain and tenderness, with fever and systemic upset, suggest extension of the infection to the pelvis and kidney, known as pyelitis or pyelonephritis. However, localization of the site of infection on the basis of symptoms alone is unreliable.

UTI also presents with minimal or no symptoms or may be associated with atypical symptoms such as abdominal pain, fever or haematuria in the absence of frequency or dysuria.

In small children, who cannot complain of dysuria, symptoms are often 'atypical'. The possibility of UTI must always be considered in the fretful, febrile sick child who fails to thrive.

Diagnosis

This is based on quantitative culture of a clean-catch mid-stream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI, particularly in symptomatic women, are shown in Table 12.10. Most Gram-negative organisms reduce nitrites to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests positive for both nitrite and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

Abacteriuric frequency or dysuria ('urethral syndrome')

Causes of truly abacteriuric frequency/dysuria include post-coital bladder trauma, vaginitis, atrophic vaginitis or urethritis in the elderly, and interstitial cystitis (Hunner's ulcer). In

symptomatic young women with 'sterile pyuria', *Chlamydia* infection and tuberculosis must be excluded.

Interstitial cystitis is an uncommon but distressing complaint, most often affecting women over the age of 40 years. It presents with frequency, dysuria and often severe suprapubic pain. Urine cultures are sterile. Cystoscopy shows typical inflammatory changes with ulceration of the bladder base. It is commonly thought to be an autoimmune disorder. Various treatments are advocated with variable success. These include oral prednisolone therapy, bladder instillation of sodium cromoglycate or dimethyl sulphoxide and bladder stretching under anaesthesia.

Predominant frequency and passage of small volumes of urine ('irritable bladder') is possibly consequent on previous UTI or conditioned by psychosexual factors. Such patients must be distinguished from those with frequency due to polyuria. Repeated courses of antibiotics in patients with genuine abacteriuric frequency or dysuria are quite inappropriate and detract from identifying the true nature of the problem.

Special investigations

Uncomplicated UTI usually does not require radiological evaluation unless it is recurrent or affecting males and children or there are unusually severe symptoms. Patients with predisposing conditions such as diabetes mellitus or immunocompromised states benefit from early imaging.

- **Ultrasound** is used in the assessment of patients with suspected pyelonephritis that requires drainage. This allows the detection of calculi, obstruction and also incomplete emptying.
- **CT** is a more sensitive modality for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied and can define the extent of disease and identify significant complications or obstruction.
- **MRI** is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.
- **Nuclear medicine** has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function and detection of scars by DMSA scan, often prior to surgery.

Treatment

Single isolated attack

Pre-treatment urine culture is desirable.

- **Antibiotics** for 3–5 days with amoxicillin (250 mg three times daily), nitrofurantoin (50 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin. The treatment regimen is modified in light of the result of urine culture and sensitivity testing, and/or the clinical response.
- For **resistant organisms** the alternative drugs are co-amoxiclav or ciprofloxacin.
- **Single-shot treatment** with 3 g of amoxicillin or 1.92 g of co-trimoxazole is used for patients with bladder symptoms of less than 36 hours' duration who have no previous history of UTI.
- **A high (2 L daily) fluid intake** should be encouraged during treatment and for some subsequent weeks. Urine culture should be repeated 5 days after treatment.
- **If the patient is acutely ill with high fever, loin pain and tenderness** (acute pyelonephritis), antibiotics

are given intravenously, e.g. aztreonam, cefuroxime, ciprofloxacin or gentamicin (2–5 mg/kg daily in divided doses), switching to a further 7 days' treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.

- **In patients presenting for the first time with high fever, loin pain and tenderness**, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present it should be drained by percutaneous nephrostomy (p. 570).

Recurrent infection

Pre-treatment and post-treatment urine cultures are necessary to confirm the diagnosis and identify whether recurrent infection is due to relapse or reinfection.

Relapse. A search should be made for a cause (e.g. stones or scarred kidneys), and this should be eradicated. Intense or prolonged treatment – intravenous or intramuscular aminoglycoside for 7 days or oral antibiotics for 4–6 weeks – is required. If this fails, long-term antibiotics are required.

Reinfection implies that the patient has a predisposition to periurethral colonization or poor bladder defence mechanisms. Contraceptive practice should be reviewed and the use of a diaphragm and spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see below). All patients must undertake prophylactic measures:

- A 2 L daily fluid intake
- Voiding at 2–3-hour intervals with double micturition if reflux is present
- Voiding before bedtime and after intercourse
- Avoidance of spermicidal jellies and bubble baths and other chemicals in bath water
- Avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6–12 months with low-dose prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and reinfection by 12–20% but studies are limited.

Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a urinary pathogen is common after a urinary catheter has been present for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in situ, antibiotic treatment is likely to be ineffective and will encourage the development of resistant organisms. Treatment with antibiotics is indicated only if the patient has symptoms or evidence of infection, and should be accompanied by replacement of the catheter. When changing catheters, a single injection of gentamicin is recommended.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection or those who are immunosuppressed, and should consist of removal or replacement of the catheter. In severe infections continuous bladder irrigation with amphotericin 50 µg/mL is used.

Bacteriuria in pregnancy

The urine of all pregnant women must be cultured, as 2–6% have asymptomatic bacteriuria. While asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of premature labour. Asymptomatic bacteriuria, in the presence of previous renal disease, may predispose to pre-eclamptic toxæmia, anaemia of pregnancy, and small or premature babies. *Therefore bacteriuria must always be treated and be shown to be eradicated.* Reinfection may require prophylactic therapy. Tetracycline, trimethoprim, sulfonamides and 4-quinolones must be avoided in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may safely be used in pregnancy.

Bacterial prostatitis

Bacterial prostatitis is a relapsing infection which is difficult to treat. It presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretion. Treatment is for 4–6 weeks with drugs that penetrate into the prostate, such as trimethoprim or ciprofloxacin. Long-term low-dose treatment may be required. Prostatodynia (prostatic pain in the absence of active infection) may be a very persistent sequel to bacterial prostatitis. Amitriptyline and carbamazepine may alleviate the symptoms.

Renal carbuncle

Renal carbuncle is an abscess in the renal cortex caused by a blood-borne *Staphylococcus*, usually from a boil or carbuncle of the skin. It presents with a high swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality, as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacillin and surgical drainage.

Tuberculosis of the urinary tract

Tuberculous infection is on the increase worldwide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. In the UK, it is mainly seen in the Asian immigrant population. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for the development of ureteral stricture and a contracted bladder. Rarely, cold abscesses may form in the loin. In males the disease may present with testicular or epididymal discomfort and thickening.

Diagnosis depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitating lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Diagnosis of active infection depends on culture of mycobacteria from early-morning urine samples. Imaging may be normal in diffuse interstitial renal tuberculosis

Figure 12.32 Renal tuberculosis.

(b) Ziehl-Neelsen staining showing mycobacteria (arrow).

when diagnosis is made by renal biopsy demonstrating caseating granuloma with multinucleate giant cells and acid-fast bacilli on Ziehl-Neelsen staining (Fig. 12.32). Some patients present with small unobstructed kidneys, when the diagnosis is easy to miss.

Treatment. The treatment is as for pulmonary tuberculosis (see p. 842). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment as ureteric strictures may first develop in the healing phase.

Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and urinary tract infection. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

TUBULOINTERSTITIAL NEPHRITIS (TIN)

Diseases of the kidney primarily affect the glomeruli, vasculature, or the remainder of the renal parenchyma that consists of the tubules and interstitium. Although the tubules and the interstitium are distinct functional entities, they are intimately related. Injury involving one of them invariably results in damage to the other.

Acute tubulointerstitial nephritis (TIN)

In approximately 70% of the cases, acute TIN is due to a hypersensitivity reaction to drugs (Table 12.11), most commonly drugs of the penicillin family and non-steroidal anti-inflammatory drugs (NSAIDs).

Drug induced acute TIN. Patients present with fever, arthralgia, skin rashes and acute oliguric or non-oliguric kidney injury. Many have eosinophilia and eosinophiluria. Renal histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis (Fig. 12.33). Rarely, NSAIDs can cause a glomerular minimal-change lesion in addition to TIN and present as the nephrotic syndrome. Treatment involves withdrawal of offending drugs. High-dose steroid therapy (prednisolone 60 mg daily) is commonly given but its efficacy has not been proven. Patients may require dialysis for management of the acute kidney injury. Most patients make a good recovery in kidney function, but some may be left with significant interstitial fibrosis and CKD.

Bacteria, e.g. streptococci	
Idiopathic (8%)	
Tubulointerstitial nephritis with uveitis (TINU) (5%)	
Systemic inflammatory disorders, e.g. systemic lupus erythematosus (SLE) (2%)	

Infection causing acute TIN. Acute pyelonephritis leads to inflammation of the tubules, producing a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (Hantavirus, Epstein-Barr virus, HIV, measles, adenovirus), bacteria (*Legionella*, *Leptospira*, streptococci, *Mycoplasma*, *Brucella*, *Chlamydia*) and others (*Leishmania*, *Toxoplasma*). Hantavirus causes haemorrhagic fever with TIN and can be fatal. Epstein-Barr virus DNA has been found in renal biopsy tissue of cases of idiopathic TIN. In immunocompromised patients such as post-renal transplantation, CMV, polyoma, and HSV can cause acute TIN in the renal graft. Treatment involves eradication of infection by appropriate antibiotics or antiviral agents and in renal transplantation modifying immunosuppressive regimen.

Acute TIN as part of multisystem inflammatory diseases. Several non-infectious inflammatory disorders such as Sjögren's syndrome, SLE and Wegener's granulomatosis can cause acute or chronic TIN rather than glomerulonephritis. Sjögren's syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes acute kidney injury. These heterogeneous conditions with TIN generally respond to steroids.

TINU syndrome. In this syndrome, uveitis generally coincides with acute TIN. It is common in childhood, but has been reported in adulthood. Among adults it is more common in females, but its cause remains unknown. Available evidence suggests that it is associated with autoantibodies directed against modified C-reactive protein. Patients present with weight loss, anaemia and raised ESR. A prolonged course of

steroids leads to improvement in both renal function and uveitis.

Chronic tubulointerstitial nephritis

The major causes of chronic tubulointerstitial nephritis are given in Table 12.12. It is characterized by generalized chronic inflammatory cellular infiltration of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis. In many cases no cause is found. Chronic TIN changes evolve into progressive primary glomerular or vascular disease of the kidney, where its severity is a better predictor of long-term renal survival than the primary site of insult.

The patient usually presents with either polyuria and nocturia, or is found to have proteinuria or uraemia. Proteinuria is usually slight (<1 g daily). Papillary necrosis with ischaemic damage to the papillae occurs in a number of tubulointerstitial nephritides, for example in analgesic abuse, diabetes mellitus, sickle cell disease or trait. The papillae can separate and be passed in the urine. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 12.34) or obstructive uropathy which is usually accompanied by tubular dilatation and atrophy and intense interstitial fibrosis with patchy inflammatory cellular infiltrate in the scarred areas.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and uraemia.

Analgesic nephropathy

The chronic consumption of large amounts of analgesics (especially those containing phenacetin) and NSAIDs leads to chronic tubulointerstitial nephritis and papillary necrosis. Analgesic nephropathy is twice as common in women as in men and presents typically in middle age. Patients are often depressed or neurotic. Presentation may be with anaemia, CKD, UTIs, haematuria or urinary tract obstruction (owing to sloughing of a renal papilla). Salt and water-wasting renal disease may occur. Chronic analgesic abuse also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the

Papillary necrosis

Always bilateral

Reflux nephropathy

May be unilateral

Figure 12.34 A comparison of radiological appearances of papillary necrosis and reflux nephropathy.

non-pathognomonic appearance on imaging (such as ultrasonography or CT scan), which demonstrates smallish irregularly outlined kidneys.

The consumption of the above analgesics should be discouraged. If necessary, dihydrocodeine or paracetamol is a reasonable alternative. This may result in the arrest of the disease and even in improvement in function. UTI, hypertension (if present) and saline depletion will require appropriate management. The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

Chinese herb nephropathy

Chinese herbal medicines have been increasingly used in the West, e.g. for slimming, and have caused a nephropathy. The renal histology is similar to Balkan nephropathy but the clinical course is very aggressive. The causal agent has been identified as aristolochic acid produced as a result of fungal contamination of the herbal medicine. It is characterized by relentless progression to ESKD. There is a high incidence of uroepithelial tumours.

Balkan nephropathy (BN)

This is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, which are subjected to frequent flooding and where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the water supply. Its cause was essentially unknown. However, new research suggests that chronic dietary poisoning by aristolochic acid (AA) is responsible for BN and its associated urothelial cancer. AA-DNA adduct is found in tissue biopsies both from BN and associated urothelial cancers. This research suggests that AA is the environmental agent responsible for BN and its associated transitional-cell cancer. The disease is insidious in onset, with mild proteinuria progressing to ESKD in 3 months to 10 years. There is no treatment.

Appel GB. The treatment of acute interstitial nephritis: more data at last. *Kidney Int* 2008; 73(8):905–907.

Figure 12.35 Granulomatous tubulointerstitial nephritis. The granuloma consists of both giant cells (arrow) and epithelioid cells. These findings are characteristic of *renal sarcoid* but can be seen with any cause (drug or infection) of interstitial nephritis.

Other forms of chronic tubulointerstitial nephritis

These are rare (Table 12.12). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable tubulointerstitial nephritis such as granulomatous TIN due to *renal sarcoidosis* (Fig. 12.35), which may be the first presentation of sarcoidosis (see p. 846). Renal sarcoidosis generally responds rapidly to steroids.

Hyperuricaemic nephropathy

Acute hyperuricaemic nephropathy (see p. 503) is a well-recognized cause of acute kidney injury in patients with marked hyperuricaemia that is usually due to lymphoproliferative or myeloproliferative disorders. It may occur prior to treatment but most often follows commencement of treatment, when there is rapid lysis of malignant cells, release of large amounts of nucleoprotein and increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters. The condition is manifest as oliguria or anuria with increasing uraemia. There may be flank pain or colic. Plasma urate levels are above 0.75 mmol/L and may be as high as 4.5 mmol/L. **Diagnosis** is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extrarenal obstruction due to stones, but a negative scan does not exclude this where there is coexistent intrarenal obstruction.

Allopurinol 100–200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid and the urine kept alkaline by the administration of sodium bicarbonate 600 mg four times daily and acetazolamide 250 mg three times daily, since uric acid is more soluble in an alkaline than in an acid medium. Febuxostat, a non-purine-analogue inhibitor of xanthine oxidase, can be used if allopurinol cannot be tolerated and eGFR is >30 mL/min. **Rasburicase**, a recombinant urate oxidase (p. 449), and **pegloticase**, a pegylated uricase in development, are occasionally used. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate.

There is no convincing direct evidence for *chronic hyperuricaemia nephropathy*. However, a few observational studies have recently suggested that elevated levels of uric acid independently increase the risk for new-onset CKD, and that lowering plasma urate reduction with allopurinol has a beneficial effect in slowing the rate of progression of CKD.

HYPERTENSION AND THE KIDNEY

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests (as described on p. 780) should be performed on all hypertensive patients, but renal imaging is usually unnecessary.

The *mechanisms* responsible for the normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (p. 777). One basic concept is that the long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume, and normal blood volume at normotensive arterial pressures. Cross-transplantation experiments suggest that hypertension travels with the kidney, in that hypertension will develop in a normotensive recipient of a kidney genetically programmed for hypertension. Similarly, patients with ESKD due to hypertension become normotensive after receiving a renal allograft from normotensive donors, provided the new kidney works.

One of many renal factors involved in the genesis of hypertension is the total number of nephrons in the kidney. Patients with hypertension and normal renal function have a significantly reduced number of nephrons in each kidney alongside enlargement of the remaining glomeruli due to glomerular hyperfiltration. Moreover, certain races (black, Hispanics) with predilection for hypertension have increased glomerular volume, a surrogate marker for a reduced number of nephrons.

Whether the reduced number of nephrons is caused by genetic or environmental factors is unclear. Changes in the intrauterine environment may lead to retarded renal growth before birth and low birth weight and hypertension during adult life. In humans, an association has been found between low birth weight and reduced renal volume, possibly indicating reduced numbers of nephrons.

Essential hypertension Pathophysiology

In benign essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur as follows:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an 'onion skin' appearance.
- Reduction in size of both kidneys occurs; this may be asymmetrical if one major renal artery is more affected than the other.
- The proportion of sclerotic glomeruli is increased compared with age-matched controls.

Deterioration in excretory function accompanies these changes, but severe CKD is unusual in whites (1 in 10000). In black Africans, by contrast, hypertension much more often results in the development of CKD with a fourfold higher incidence of ESKD in blacks compared to whites. This racial difference in incidence of hypertensive renal disease may be due to overestimation of diagnosis on clinical grounds, poor compliance with medication, higher incidence of hypertension, which is usually a salt-sensitive type, reduced number

of nephrons and possibly resulting from higher frequency of susceptibility alleles for ESKD in the West African than the European gene pool.

A recent genome-wide study found statistically stronger associations between two independent sequence variants in the apolipoprotein L1 gene (APOL1) and non-diabetic nephropathy in African Americans, in hypertension-attributed ESKD. These kidney disease risk variants most likely arose due to positive selection for evolutionary advantage these variants in APOL1 conferred against trypanosomal infection and protection from African sleeping sickness. These observations provide some evidence, similar to findings with sickle cell anaemia, that natural selection might protect from one disease but allow another one to develop.

In *accelerated or malignant-phase hypertension*:

- Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles.
- Fibrin deposition within small vessels is often associated with thrombocytopenia and red-cell fragmentation seen in the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria, usually of modest degree (1–3 g daily), and progressive uraemia occur. If untreated, fewer than 10% of patients survive 2 years.

Management

The management of benign essential and malignant hypertension is described on page 781.

If treatment is begun before CKD has developed, the prognosis for renal function is good. Stabilization or improvement in renal function with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis occur with effective treatment of malignant phase hypertension. In blacks with hypertensive nephrosclerosis and CKD, a blood pressure target of <140/85 mmHg should be achieved.

Renal hypertension

Hypertension commonly complicates bilateral renal disease such as chronic glomerulonephritis, bilateral reflux nephropathy, polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

- Activation of the renin-angiotensin-aldosterone system
- Retention of salt and water owing to impairment in excretory function, leading to an increase in blood volume and hence blood pressure.

The second of these assumes greater significance as renal function deteriorates.

Hypertension occurs earlier, is more common and tends to be more severe in patients with renal cortical disorders, such as glomerulonephritis, than in those with disorders affecting primarily the renal interstitium, such as reflux or analgesic nephropathy.

Management is described on page 781. Meticulous control of the blood pressure is necessary to prevent further deterioration of renal function secondary to vascular changes produced by the hypertension itself. There is good evidence that ACE-inhibitor drug treatment confers an additional renoprotective effect for a given degree of blood pressure control than other hypotensive drugs. In a study of African Americans with hypertension, intensive blood pressure control (130/78) was not superior to standard control (141/86) in the prevention of ESKD. However, in the same study patients with

proteinuria (protein creatinine ratio >0.22) benefited more from intensive blood pressure control.

Renovascular disease

Mechanism of hypertension

Renal ischaemia results in a reduction in the pressure in afferent glomerular arterioles. This leads to an increase in the production and release of renin from the juxtaglomerular apparatus (see p. 567) with a consequent increase in angiotensin II, a very potent vasoconstrictor. Angiotensin II also causes hypertension by upregulating NADPH oxidase enzyme with excessive superoxide generation. Superoxide chelates nitric oxide (a potent vasodilator) resulting in reduced vasodilator activity and also hypertension.

Physiological changes in renal artery stenosis

In renal artery stenosis, renal perfusion pressure is reduced and nephron transit time is prolonged on the side of the stenosis; salt and water reabsorption is therefore increased. As a result, urine from the ischaemic kidney is more concentrated and has a lower sodium concentration than urine from the contralateral kidney. Creatinine clearance is decreased on the ischaemic side.

Pathology

Narrowing of the renal arteries (renal artery stenosis) is caused by one of two pathological entities: *fibromuscular disease* or *atherosclerotic renovascular disease (ARVD)*.

Fibromuscular disease of the renal arteries

Fibromuscular disease (FMD) accounts for 20–40% of renal vascular disease and encompasses *four distinct types*: (1) medial fibroplasia (65–85%); (2) perimedial fibroplasia (10–15%); (3) intimal fibroplasia (5–10%); and (4) medial hyperplasia (5%). Medial fibroplasia usually follows a benign course and never follows a progressive course after the age of 40 years. The other two types of fibroplasia follow a progressive course and may lead to total occlusion.

Medial hyperplasia is a distinct but rare entity, which accounts for only 1% of renovascular disease. It commonly affects young females, who exhibit elevated blood pressures but with well-preserved renal function.

MR angiography (gadolinium enhanced) reveals a characteristic string of beads appearance in fibroplasia.

Angioplasty (occasionally stent insertion) or surgery is usually performed in affected individuals. Cure rates were only 36% and 54% after angioplasty and surgery, respectively, in a recent study of over 2000 patients (defining cure as blood pressure <140/90 mm Hg without treatment), and the blood pressure outcome was strongly age related. Furthermore, the incidence of complications was substantial: combined risks of periprocedural complications were 12% after angioplasty and 17% after surgery, with fewer major complications after angioplasty (6%) than after surgery (15%). Given the efficacy of current medical antihypertensive therapy, intervention in these patients is usually not warranted.

Atherosclerotic renovascular disease (ARVD)

This is a common cause of hypertension and CKD due to ischaemic nephropathy. Its incidence increases with age, rising from 5% under 60 years to 16% in those over 60 years old. In most patients, the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease

(39%), coronary artery disease (10–29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. The renal consequences of ARVD are functional, such as hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually sub-nephrotic range) and decreased GFR. The morphological features of the affected kidneys include vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli and secondary focal segmental glomerulosclerosis (FSGS) changes. Baseline renal function is related to the extent of renal parenchymal injury rather than to the degree of stenosis, as is the response (improvement in hypertension and renal function) to revascularization.

Renovascular disease should be looked for in the following: patients with hypertension and/or CKD; patients with abdominal audible bruits, as well as bruits over carotid arteries suggestive of generalized arterial disease; Doppler ultrasonography showing >1.5 cm renal asymmetry; recurrent flash pulmonary oedema without cardiopulmonary disease; and lastly, progressive CKD in patients with evidence of generalized atherosclerosis.

Treatment

The *aim of treatment* is to correct hypertension and improve renal perfusion and excretory function. Renal artery stenosis can progress to occlusion, particularly in patients with stenosis >75% as shown by serial angiography, necessitating revascularization in ARVD.

- The **options in renal artery stenosis** include transluminal angioplasty to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, rendering angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy.
- **Indications for revascularization.** Vessels with stenosis >75% and recurrent flash pulmonary oedema, drug-resistant severe hypertension, ARVD affecting solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive CKD and dialysis-dependent renal failure. Generally, endovascular procedures are considered better than medical therapy alone and, with good selection of patients, hypertension is cured or improved by intervention in more than 50%. Occasional dramatic improvements in renal function ensue but results are generally disappointing. Deterioration of the renal function occurs in 20–30% of the patients after renal angioplasty stenting. Atheroembolism seems to play a role and is probably the main cause of this renal function deterioration.
- **Medication.** All patients with ARVD should be treated with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis.

Prognosis. Mortality is high because of other associated co-morbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with ESKD have higher rates

than those with good renal function. Five-year survival is only 18% in patients with ESKD due to ARVD.

Screening for renovascular disease

Radionuclide studies (see p. 571). These can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis, a disproportionate fall in uptake of isotope on the affected side following administration of captopril or aspirin is suggestive of the presence of significant renal artery stenosis. A completely normal result renders the diagnosis unlikely.

Doppler ultrasound. This method is very sensitive but highly operator-dependent and time-consuming. Measurement of renal-artery velocity by Doppler ultrasound provides a functional assessment of the severity of stenosis; higher velocity usually means higher pressure differential across the stenosis. It also generates useful data about intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of >80 is a predictor of poor response following intervention.

Magnetic resonance angiography. MRA can be used to visualize the renal arteries and there is a good – though not perfect – correlation between MRA findings and those of renal arteriography.

CT scanning. This permits non-invasive imaging of the renal arteries. It is much less expensive than MRA but does expose the patient to ionizing radiation and to contrast injection and is less reliable than MRA.

Renal arteriography (see this chapter) is used to confirm the diagnosis of renal arterial disease.

OTHER VASCULAR DISORDERS OF THE KIDNEY

Renal artery occlusion

This occurs from thrombosis in situ, usually in a severely damaged atherosclerotic vessel, or more commonly from embolization, e.g. in atrial fibrillation. Both lead to renal infarction, resulting in a wide spectrum of clinical manifestations depending on the size of the artery involved. Occlusion of a small branch artery may produce no effect, but occlusion of larger vessels results in dull flank pain and varying degrees of CKD.

Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization or atheroembolic renal disease (AERD)

Showers of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, e.g. to the retina or digits. The diagnosis can be confirmed by renal biopsy (Fig. 12.36). It is more common in males, the elderly (>70 years) and patients with cardiovascular disease. Over 80% have abnormal renal function at baseline. AERD occurs spontaneously in 25% of the cases. The 2-year mortality is 30% and a similar percentage of patients develop CKD. Baseline co-morbidities, i.e.

Table 12.13 Type and frequency of renal stones in the UK

Type of renal stone	Percentage of stones
Calcium oxalate usually with calcium phosphate	65
Calcium phosphate alone	15
Magnesium ammonium phosphate (struvite)	10–15
Uric acid	3–5
Cystine	1–2

reduced renal function, presence of diabetes, history of heart failure, acute/subacute presentation, and gastrointestinal tract involvement, are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those receiving statins.

Renal vein thrombosis

This is usually of insidious onset, occurring in patients with the nephrotic syndrome, with a renal cell carcinoma, and in thrombophilia (p. 424) with an increased risk of venous thrombosis. Anticoagulation is indicated.

RENAL CALCULI AND NEPHROCALCINOSIS

Renal and vesical calculi

Renal stones are very common worldwide, with a lifetime risk of about 10%. Prevalence of stone disease is much higher in the Middle East. Most stones occur in the upper urinary tract.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Table 12.13). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2:1.

Stone disease is frequently a recurrent problem. More than 50% of patients with a history of nephrolithiasis will develop a recurrence within 10 years. The risk of recurrence increases if a metabolic or other abnormality predisposing to stone formation is present and is not modified by treatment. Nephrolithiasis is not a benign condition as several observational studies have demonstrated its association with increased risk of ESKD, bone diseases, hypertension and myocardial infarction.

Aetiology

Inhibitors of crystal formation are present in normal urine preventing the formation of stones, as the concentrations of stone-forming substances in many cases exceed their maximum solubility in water. Many stone-formers have no detectable metabolic defect, although microscopy of warm, freshly passed urine reveals both more and larger calcium oxalate crystals than are found in normal subjects. Factors predisposing to stone formation in these so-called 'idiopathic stone-formers' are:

- Chemical composition of urine that favours stone crystallization
- Production of a concentrated urine as a consequence of dehydration associated with life in a hot climate or work in a hot environment
- Impairment of inhibitors that prevent crystallization in normal urine. Postulated inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation.

Recognized causes of stone formation are listed in Table 12.14.

Hypercalcaemia

If the GFR is normal, hypercalcaemia almost invariably leads to hypercalciuria. The common causes of hypercalcaemia leading to stone formation are:

- Primary hyperparathyroidism
- Vitamin D ingestion
- Sarcoidosis.

Of these, primary hyperparathyroidism (see p. 994) is the most common cause of stones.

Hypercalciuria

This is by far the most common metabolic abnormality detected in calcium stone-formers.

Approximately 8% of men excrete in excess of 7.5 mmol of calcium in 24 hours. Calcium stone formation is more common in this group, but as the majority of even these individuals do not form stones the definition of 'pathological' hypercalciuria is arbitrary. A reasonable definition is 24-hour calcium excretion of >7.5 mmol in male stone-formers and >6.25 mmol in female stone-formers.

The kidney is the major site for plasma calcium regulation. Approximately 90% of the ionized calcium filtered by the kidney is reabsorbed. Renal tubular reabsorption is controlled largely by parathyroid hormone (PTH).

Approximately 65% of the filtered calcium is absorbed in the proximal convoluted tubule, 20% by the thick ascending

limb of the loop of Henle, and 15% by the distal convoluted tubule and collecting ducts.

Causes of hypercalciuria are:

- Hypercalcaemia
- An excessive dietary intake of calcium
- Excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- Idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and uncontrolled hypercalciuria is a cause of recurrences. The majority of patients with idiopathic hypercalciuria have increased absorption of calcium from the gut. Moreover, studies have shown that animal protein and salt also have a considerable influence on calcium excretion.

Hyperoxaluria

There are two inborn errors of glyoxalate metabolism that cause increased endogenous oxalate biosynthesis and are inherited in an autosomal recessive manner:

- **Type 1:** alanine-glyoxylate aminotransferase deficiency
- **Type 2:** glyoxylate reductase hydroxypyruvate reductase deficiency.

In both types, calcium oxalate stone formation occurs.

The prognosis is poor owing to widespread calcium oxalate crystal deposition in the kidneys. CKD typically develops in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- Excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- Dietary calcium restriction, with compensatory increased absorption of oxalate
- Gastrointestinal disease (e.g. Crohn's), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

Hyperuricaemia and hyperuricosuria

Uric acid stones account for 3–5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the endpoint of purine metabolism. Hyperuricaemia (see

p. 530) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, e.g. in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 hours on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with ileostomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

Urinary tract infection

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (staghorn calculus). These stones are usually due to UTI with organisms such as *Proteus mirabilis* that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

Cystinuria (see also p. 1040)

Cystinuria results in the formation of cystine stones. About 1–2% of all stones are composed of cystine.

Primary renal diseases

- **Polycystic renal disease** (see p. 632) shows a high prevalence of stone disease.
- **Medullary sponge kidney** is also associated with stones. There is dilatation of the collecting ducts with associated stasis and calcification (Fig. 12.37). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
- **Renal tubular acidoses**, both inherited and acquired, are associated with nephrocalcinosis and stone formation, owing, in part, to the production of a persistently alkaline urine and reduced urinary citrate excretion.

a

b

Figure 12.37 Medullary sponge kidney. (a) Plain film showing 'spotty' calcification in the renal areas (arrow). **(b)** After injection of contrast, the calcification is shown to be small calculi in the papillary zones.

Drugs

Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates); and some precipitate into stones (e.g. indinavir, triamterene, sulphadiazine).

Aetiology of bladder stones

Bladder stones are endemic in some developing countries but the incidence is declining. The cause of this is unknown but dietary factors probably play a role. Bladder stones may be the result of:

- bladder outflow obstruction (e.g. urethral stricture, neuropathic bladder, prostatic obstruction)
- the presence of a foreign body (e.g. catheters, non-absorbable sutures).

Significant bacteriuria is usually found in patients with bladder stones. Some stones found in the bladder have been passed down from the upper urinary tract.

Pathology

Stones may be single or multiple and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Pressure necrosis from a large calculus can cause direct damage to the renal parenchyma, and stones regularly cause obstruction, leading to hydronephrosis. They may ulcerate through the wall of the collecting system, including the ureter. A combination of obstruction and infection accelerates damage to the kidney.

Clinical features

Most people with urinary tract calculi are asymptomatic. Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (Table 12.15).

When urinary tract obstruction is present, measures that increase urine volume, such as copious fluid intake or diuretics, including alcohol, make the pain worse. Physical exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria. Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. This is one of the most severe pains known. Radiation from the flank to the iliac fossa and testis or labium in the distribution of the first lumbar nerve root is common. Pallor, sweating and vomiting often occur and the patient is restless, trying to obtain relief from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicaemia may dominate the clinical picture.

Vesical calculi associated with bladder bacteriuria present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present. A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

Table 12.15 Clinical features of urinary tract stones

Asymptomatic	Urinary tract infection
Pain: renal colic	Urinary tract obstruction
Haematuria	

A history of possible aetiological factors should be obtained, including:

- Occupation and residence in hot countries likely to be associated with dehydration
- A history of vitamin D consumption
- Gouty arthritis.

Calcified papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered.

Physical examination should include a search for corneal or conjunctival calcification, gouty tophi and arthritis and features of sarcoidosis.

Investigations

- **A mid-stream specimen of urine** for culture
- **Serum urea, electrolyte, creatinine (eGFR) and calcium levels.**
- **Plain abdominal X-ray**
- **CT-KUB** is the best diagnostic test available. Ureteric stones can be missed by ultrasound.

CT-KUB (CT of kidney, ureter and bladder) is carried out during the episode of pain; a normal CT excludes the diagnosis of pain due to calculous disease. The CT-KUB appearances in a patient with acute left ureteric obstruction are shown in Figure 12.38.

Figure 12.38 CT-KUB in ureteric stone obstruction. (a) Left ureteric calculus. (b) A dilated renal pelvis (arrow) proximal to the ureteric stone in (a).

Figure 12.39 CT scan, showing a uric acid stone, which appears as a bright lesion in the left kidney (arrow).

Pure uric acid stones are radiolucent and show as a filling defect after injection of contrast medium if excretion urography is performed. Such stones are readily seen on CT scanning (Fig. 12.39). Mixed infective stones in which organic matrix predominates are barely radiopaque.

The urine of the patient should be passed through a sieve to trap any calculi for chemical analysis.

Management

Adequate analgesia should be given. An NSAID, e.g. diclofenac 75 mg by i.v. infusion, compares favourably with pethidine and does not cause nausea. Stones less than 0.5 cm diameter usually pass spontaneously. Alpha blockers (e.g. tamsulosin) facilitate spontaneous expulsion of distal ureteral stones of <6 mm size and should be tried first as alpha receptors are predominantly present in distal ureter and detrusor and this strategy is very cheap and has a high safety profile.

Stones >1 cm diameter usually require urological or radiological intervention. Extracorporeal shock wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a YAG laser can be used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

Investigating the cause of stone formation

In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation require detailed investigation.

- **Renal imaging** is necessary to define the presence of a primary renal disease predisposing to stone formation.
- **Significant bacteriuria** may indicate mixed infective stone formation, but relapsing bacteriuria may be a consequence of stone formation rather than the original cause.
- **Chemical analysis** of any stone passed is of great value and all that is required in the diagnosis of cystinuria or uric acid stone formation.
- **Serum calcium concentration** should be estimated and corrected for serum albumin concentration (see p. 634). Hypercalcaemia, if present, should be investigated further (see p. 995).
- **Serum urate concentration** is often, but not invariably, elevated in uric acid stone-formers.
- **A screening test for cystinuria** should be carried out by adding sodium nitroprusside to a random unacidified

urine sample; a purple colour indicates that cystinuria may be present. Urine chromatography is required to define the diagnosis precisely.

- **Urinary calcium, oxalate and uric acid output** should be measured in two consecutive carefully collected 24-hour urine samples. After withdrawing aliquots for estimation of uric acid, it is necessary to add acid to the urine in order to prevent crystallization of calcium salts upon the walls of the collection vessel, which would give falsely low results for urinary calcium and oxalate.
- **Plasma bicarbonate** is low in renal tubular acidosis. The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see p. 664).

Prophylaxis

The age of the patient and the severity of the problem affect both the need for and the type of prophylaxis.

Idiopathic stone-formers

Where no metabolic abnormality is present, the mainstay of prevention is maintenance of a high intake of fluid throughout the day and night. The aim should be to ensure a daily urine volume of 2–2.5 L, which requires a fluid intake in excess of this, substantially so in the case of those who live in hot countries or work in a hot environment.

Idiopathic hypercalciuria

Severe dietary calcium restriction is inappropriate (see p. 627) and patients should be encouraged to consume a normal-calcium (30 mmol/day) diet. Dietary calcium restriction results in hyperabsorption of oxalate, and so foods containing large amounts of oxalate should also be limited. A high fluid intake should be advised as for idiopathic stone-formers. Patients who live in a hard-water area may benefit from drinking softened water.

If hypercalciuria persists and stone formation continues, a thiazide is used (e.g. bendroflumethiazide 2.5 or 5 mg each morning). Thiazides reduce urinary calcium excretion by an indirect effect due to mild volume contraction resulting in increased calcium absorption in the proximal renal tubule. They may precipitate diabetes mellitus or gout and worsen hypercholesterolaemia. Reduction of animal proteins to 50 g/day and sodium intake to 50 mmol/day is also advisable.

Mixed infective stones

Recurrent stones should be prevented by maintenance of a high fluid intake and meticulous control of bacteriuria. This will require long-term follow-up and often the use of long-term low-dose prophylactic antibacterial agents.

Uric acid stones

Dietary measures are probably of little value and are difficult to implement. Effective prevention can be achieved by the long-term use of allopurinol to maintain the serum urate and urinary uric acid excretion in the normal range. A high fluid intake should also be maintained. Uric acid is more soluble at alkaline pH, and long-term sodium bicarbonate supplementation to maintain an alkaline urine is an alternative approach in those few patients unable to take allopurinol (see p. 995). However, alkalinization of the urine facilitates precipitation of calcium oxalate and phosphate.

Cystine stones

These can be prevented and indeed will dissolve slowly with a high fluid intake. Five litres of water is drunk each 24 hours, and the patient must wake twice during the night to ingest

500 mL or more of water. Many patients cannot tolerate this regimen. Alkalinization to a pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is the long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine-cystine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present. Other cystine-binding drugs include tiopronin which may lower incidence of side-effects compared with penicillamine and is sometimes preferred.

Mild hyperoxaluria with calcium oxalate stones

Hyperoxaluria can result from rare monogenetic conditions. Type 1 can be managed with oral high-dose pyridoxine, but type 2 is unlikely to respond to it. Unfortunately, there is currently no proven pharmacotherapy to effectively treat the more common form of 'idiopathic' hyperoxaluria present in up to 40% of stone formers. Probiotic *Oxalobacter formigenes* has shown some promise.

Current advice for idiopathic hyperoxaluria patients includes high fluid intake and dietary oxalate restriction. Dietary advice as in hypercalciuria is also advisable.

Nephrocalcinosis

The term 'nephrocalcinosis' means diffuse renal parenchymal calcification that is detectable radiologically (Fig. 12.40). The condition is typically painless. Hypertension and CKD commonly occur. The main causes of nephrocalcinosis are listed in Table 12.16.

Dystrophic calcification occurs following renal cortical necrosis. In *hypercalcaemia* and *hyperoxaluria*, deposition

of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In **renal tubular acidosis** (see p. 664) failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Treatment and prevention of nephrocalcinosis consists of treatment of the cause.

URINARY TRACT OBSTRUCTION

The urinary tract can be obstructed at any point between the kidney and the urethral meatus. This results in dilatation of the tract above the obstruction. Dilatation of the renal pelvis is known as hydronephrosis.

Aetiology

Obstructing lesions may lie within the lumen, or in the wall of the urinary tract, or outside the wall, causing obstruction by external pressure. The major causes of obstruction are shown in Table 12.17. Overall, the frequency is the same in men and women. However, in the elderly, urinary tract obstruction is more common in men owing to the frequency of bladder outflow obstruction from prostatic disease.

Pathophysiology

Obstruction with continuing urine formation results in:

- Progressive rise in intraluminal pressure
- Dilatation proximal to the site of obstruction
- Compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilatation succeeded by vasoconstriction, probably

Table 12.17 Causes of urinary tract obstruction

Within the lumen
Calculus
Blood clot
Sloughed papilla (diabetes; analgesia abuse; sickle cell disease or trait)
Tumour of renal pelvis or ureter bladder tumour
Within the wall
Pelviureteric neuromuscular dysfunction (congenital, 10% bilateral)
Ureteric stricture (tuberculosis, especially after treatment; calculus; after surgery)
Ureterovesical stricture (congenital; ureterocele; calculus; schistosomiasis)
Congenital megaureter
Congenital bladder neck obstruction
Neuropathic bladder
Urethral stricture (calculus; gonococcal; after instrumentation)
Congenital urethral valve
Pin-hole meatus
Pressure from outside
Pelviureteric compression (bands; aberrant vessels)
Tumours (e.g. retroperitoneal tumour or glands; carcinoma of colon; tumours in pelvis, e.g. carcinoma of cervix)
Diverticulitis
Aortic aneurysm
Retroperitoneal fibrosis (periaortitis)
Accidental ligation of ureter
Retrocaval ureter (right-sided obstruction)
Prostatic obstruction
Phimosis

mediated mainly by angiotensin II and thromboxane A₂. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

Clinical features

Symptoms of upper tract obstruction

Loin pain occurs which can be dull or sharp, constant or intermittent. It is often provoked by measures that increase urine volume and hence distension of the collecting system, such as a high fluid intake or diuretics, including alcohol. Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Conversely, polyuria may occur in partial obstruction owing to impairment of renal tubular concentrating capacity. Intermittent anuria and polyuria indicates intermittent complete obstruction.

Infection complicating the obstruction may give rise to malaise, fever and septicaemia.

Symptoms of bladder outflow obstruction

Symptoms may be minimal. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling and a sense of incomplete bladder emptying are typical features (see p. 635).

Infection commonly occurs, causing increased frequency, urgency, urge incontinence, dysuria and the passage of cloudy smelly urine. It may precipitate acute retention.

Signs

Loin tenderness may be present. An enlarged hydronephrotic kidney is often palpable. In acute or chronic retention the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is essential, since prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction. However, the apparent size of the prostate on digital examination is a poor guide to the presence of prostatic obstruction.

Investigations

- **Routine blood and biochemical investigations** show a raised serum urea or creatinine (eGFR), hyperkalaemia, anaemia of chronic disease or blood in the urine.
- **Plain abdominal X-ray** may detect radiolucent stones/calcification but can miss stones lying over the bone.
- **CT scanning** has a high sensitivity and can visualize uric acid (radiolucent) stones as small as 1 mm, as well as details of the obstruction.
- **Ultrasonography** (see p. 570) can rule out upper urinary tract dilatation. Ultrasound cannot distinguish a baggy, low-pressure unobstructed system from a tense, high-pressure obstructed one, so that false-positive scans are seen. Stones in the ureter can be missed.
- **Excretion urography** is seldom used. The nephrogram is delayed on the obstructed side, owing to a reduction in the GFR. With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilatation is seen (Fig. 12.41).
- **Radionuclide studies** (see p. 571). These have no place in the initial investigation of acute obstruction. Their main role is in possible longstanding obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.

Figure 12.41 Intravenous urographic X-ray taken 24 hours after injection of contrast, showing a delayed nephrogram and pyelogram on the left side and dilatation of the system to the level of the block. By this time, contrast medium has disappeared from the normal right side.

- **Antegrade pyelography and ureterography** (see p. 570) defines the site and cause of obstruction. It can be combined with drainage of the collecting system by percutaneous needle nephrostomy.
- **Retrograde ureterography** (see p. 571) is indicated if antegrade examination cannot be carried out or if there is the possibility of dealing with ureteric obstruction from below at the time of examination. The technique carries the risk of introducing infection into an obstructed urinary tract. In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.
- **Cystoscopy, urethroscopy and urethrogography** can visualize obstructing lesions within the bladder and urethra directly. Urethrography involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture, and taking X-ray films during voiding to show obstructing lesions in the urethra. It is of particular value in the diagnosis of urethral valves and strictures.

Treatment

The aim is to relieve symptoms and preserve renal function by:

- Relieving the obstruction
- Treating the underlying cause
- Preventing and treating infection.

Temporary external drainage of urine by nephrostomy may be valuable, as this allows time for further investigation when the site and nature of the obstructing lesion are

uncertain, doubt exists as to the viability of the obstructed kidney, or when immediate definitive surgery would be hazardous.

Recent, complete upper urinary tract obstruction demands urgent relief to preserve kidney function, particularly if infection is present.

In contrast, with partial urinary tract obstruction, particularly if spontaneous relief is expected – such as by passage of a calculus – there is no immediate urgency.

Surgical management depends on the cause of the obstruction (see below) and local expertise. Dialysis may be required in the ill patient prior to surgery.

Diuresis usually follows relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction owing to previous sodium and water overload and the osmotic effect of retained solutes combined with a defective renal tubular reabsorptive capacity (as in the diuretic phase of recovering acute tubular necrosis). This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). Defective renal tubular reabsorptive capacity cannot be the sole mechanism of severe diuresis since this phenomenon is not observed following relief of unilateral obstruction. The diuresis is usually self-limiting, but a minority of patients will develop severe sodium, water and potassium depletion requiring appropriate intravenous replacement. In milder cases, oral salt and potassium supplements together with a high water intake are sufficient.

Specific causes of obstruction

Calculi

These are discussed on [page 600](#).

Pelviureteric junction obstruction (Fig. 12.42)

This results from a functional disturbance in peristalsis of the collecting system in the absence of mechanical obstruction. Surgical attempts at correction of the obstruction by open or percutaneous pyeloplasty are indicated in patients with recurrent loin pain and those in whom serial scans or measurements of GFR indicate progressive kidney damage. Nephrectomy to remove the risk of developing pyonephrosis and septicaemia is indicated if longstanding obstruction has destroyed kidney function.

Figure 12.42 X-ray, showing left pelviureteric junction obstruction (arrow).

Obstructive megaureter

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with UTI, flank pain or haematuria. The diagnosis is made on imaging with ultrasound, CT or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with reimplantation into the bladder is always indicated in children and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

Retroperitoneal fibrosis (RPF; chronic periaortitis)

The incidence and prevalence are 0.1 per 100 000 and 1.38 per 100 000, respectively. It is three times more common in men than in women.

The ureters become embedded in dense retroperitoneal fibrous tissue with resultant unilateral or bilateral obstruction. Obstruction is usually due to loss of peristalsis rather than occlusion. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients, the fibrotic process can extend outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosing thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumour, fibrotic arthropathy, pleural, pericardial and lung fibrosis have been reported with increasing frequency.

Aetiology is either an autoallergic response to leakage of material, probably ceroid, from atheromatous plaques producing an inflammatory reaction, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF is possibly initiated as a vasa vasorum vasculitis in the aortic wall which is often seen in chronic periaortitis. This inflammatory process can cause medial wall thinning and promote atherosclerosis, and also extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic periaortitis. The autoimmune reaction to plaque antigens could be an epiphenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG4-bearing plasma cells; the latter is a common finding in autoimmune chronic pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

Pathology. The hallmark of idiopathic RPF is background sclerosis with myofibroblasts associated with a diffuse and perivascular infiltrate mainly consisting of T and B lymphocytes and IgG4 isotype bearing plasma cells. Small vessel vasculitis may be found in approximately 50% of the patients.

Causes are many but 66% are idiopathic. *Secondary causes* include drugs (methysergide, lysergic acid, ergot derived dopamine receptor agonists (cabergoline, bromocriptine, pergolide), ergotamine, methyl dopa, hydralazine, beta-blockers, malignant diseases (carcinomas of the colon, prostate, breast, stomach, carcinoid, Hodgkin's and non-Hodgkin's lymphomas, sarcomas), infections (tuberculosis, syphilis, histoplasmosis, actinomycosis and fungal infections), and surgery/radiotherapy (lymph node resection,

Figure 12.43 Retroperitoneal fibrosis (periaortitis). Note the large mass surrounding the abdominal aorta on this CT scan (arrow).

colectomy, hysterectomy, aortic aneurysm repair). Recognized associations include untreated abdominal aortic aneurysm, smoking and asbestosis.

Clinical. Malaise, low back pain, weight loss, testicular pain, claudication and haematuria occur.

Laboratory tests show normochromic anaemia, uraemia and a raised erythrocyte sedimentation rate (ESR) and CRP.

Imaging with ultrasound will show a poorly circumscribed periaortic mass. The test of choice is a contrast-enhanced CT, which will show the mass, lymph nodes and tumour (Fig. 12.43). MRI will show similar findings but does not require contrast. Positron emission tomography (PET) is helpful (see below).

Treatment. Obstruction is relieved surgically by ureterolysis. A biopsy is performed to exclude an underlying lymphoma or carcinoma. Corticosteroids are of benefit, and in bilateral obstruction in frail patients it may be best to free only one ureter and to rely upon steroid therapy to induce regression of fibrous tissue on the contralateral side, since bilateral ureterolysis is a major operation. An alternative approach is placement of a ureteric stent or stents and corticosteroid therapy, but regular (usually 6-monthly) changes of the stent or stents are required if the periaortic mass does not regress.

Management. Response to treatment and disease activity are assessed by serial measurements of ESR and eGFR supplemented by isotopic and imaging techniques including CT scanning. Fluorodeoxyglucose-PET (FDG-PET), a functional imaging modality, assesses the metabolic activity of the retroperitoneal mass. FDG-PET also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary retroperitoneal fibrosis. In idiopathic RPF, FDG-PET can be used to monitor the residual inflammatory component following medical therapy. Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen is also effective. Long-term follow-up is mandatory.

Benign prostatic hypertrophy

Benign prostatic hypertrophy is a common cause of urinary tract obstruction. It is described on [page 635](#).

Prognosis of urinary tract obstruction

The prognosis depends upon the cause and the stage at which obstruction is relieved. In obstruction, four factors

influence the rate at which kidney damage occurs, its extent and the degree and rapidity of recovery of renal function after relief of obstruction. These are:

- Whether obstruction is partial or complete
- The duration of obstruction
- Whether or not infection occurs
- The site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If the duration of complete obstruction is several months, total irreversible destruction of the affected kidney will result. Partial obstruction carries a better prognosis, depending upon its severity. Bacterial infection coincident with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck may induce hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

DRUGS AND THE KIDNEY

Drug-induced impairment of renal function

Pre-renal

Impaired perfusion of the kidneys can result from drugs that cause:

- Hypovolaemia, e.g.
 - (a) Potent loop diuretics such as furosemide, especially in elderly patients
 - (b) Renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- Decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- Decreased renal blood flow (e.g. ACE inhibitors particularly in the presence of renovascular disease).

Renal

Several mechanisms of drug-induced renal damage exist and may co-exist.

- **Acute tubular necrosis produced by direct nephrotoxicity.** Examples include prolonged or excessive treatment with aminoglycosides (e.g. gentamicin, streptomycin), amphotericin B, heavy metals or carbon tetrachloride. The combination of aminoglycosides with furosemide is particularly nephrotoxic.
- **Acute tubulointerstitial nephritis** (see [p. 595](#)) with interstitial oedema and inflammatory cell infiltration. This cell-mediated hypersensitivity nephritis occurs with many drugs, including penicillins, sulphonamides and NSAIDs (which have many other effects on the kidney; [Box 12.3](#)).
- **Chronic tubulointerstitial nephritis** due to drugs, see [page 596](#).
- **Membranous glomerulonephritis**, e.g. penicillamine, gold, anti-TNF ([p. 577](#)).

Post-renal

Retroperitoneal fibrosis with urinary tract obstruction can result from the use of drugs ([p. 606](#)).

Box 12.3 Non-steroidal anti-inflammatory drugs and the kidney

Problem	Cause
Sodium and water retention	Reduction of prostaglandin production
Acute tubulointerstitial nephritis	Hypersensitivity reaction
Nephrotic syndrome	Membranous glomerulopathy
Analgesic nephropathy	Papillary necrosis after chronic use
Acute kidney injury	Acute tubular necrosis
Hyperkalaemia	Decreased renal excretion of K^+

Box 12.4 Safe prescribing in kidney disease

Safe prescribing in CKD demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing, and discuss with the patient:

1. **Is treatment mandatory?** Unless it is, it should be withheld.
2. **Can the drug reach its site of action?** For example, there is little point in prescribing the urinary antiseptic, nitrofurantoin, in severe CKD since bacteriostatic concentrations will not be attained in the urine.
3. **Is the drug's metabolism altered in uraemia?**
4. **Will accumulation of the drug or metabolites occur?** Even if accumulation is a potential problem owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend upon the size of the patient and is unrelated to renal function. Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual or smaller doses at the usual time intervals.
5. **Is the drug toxic to the kidney?**
6. **Are the effective concentrations** of the drug in biological tissues similar to the toxic concentrations? Should blood levels of the drug be measured?
7. **Will the drug worsen the uraemic state** by means other than nephrotoxicity, e.g. steroids, tetracycline?
8. **Is the drug a sodium or potassium salt?** These are potentially hazardous in uraemia.
Not surprisingly, adverse drug reactions are more than twice as common in CKD as in normal individuals. Elderly patients, in whom unsuspected CKD is common, are particularly at risk. Attention to the above and titration of the dose of drugs employed should reduce the problem.
The dose may be titrated by:
 - Observation of its clinical effect, e.g. hypotensive agents
 - Early detection of toxic effects
 - Measurement of drug levels in the blood, e.g. gentamicin levels.

Use of drugs in patients with impaired renal function (Box 12.4)

Many aspects of drug handling are altered in patients with CKD.

Absorption

This may be unpredictable in uraemia, as nausea and vomiting are frequently present.

Metabolism

Oxidative metabolism of drugs by the liver is altered in uraemia, although this is rarely of clinical significance.

The rate of drug metabolism by the kidney is reduced as a result of two factors:

- **Reduced drug catabolism.** Insulin, for example, is in part catabolized by the normal kidney. In renal disease, insulin catabolism is reduced. The insulin requirements of diabetics decline as renal function deteriorates, for this reason.
- **Reduced conversion of a precursor to a more active metabolite,** such as the conversion of 25-hydroxycholecalciferol to the more active $1,25-(OH)_2D_3$. The 1α -hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of $1,25-(OH)_2D_3$ results.

Protein binding

Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Measurement of the total plasma concentration of such a drug can give misleading results. For example, the serum concentration of phenytoin required to produce an antiepileptic effect is much higher in normal individuals than in those with CKD, since in the latter proportionately more drug is present in the free form.

Some patients with renal disease are hypoproteinaemic and reduced drug-binding to protein results. This is not the sole mechanism of reduced drug-binding in such patients. For example, hydrogen ions, which are retained in CKD, bind to receptors for acidic drugs such as sulphonamides, penicillin and salicylates, thus enhancing their potential for causing toxicity.

Volume of distribution

Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity

The renal response to drug treatment may be reduced in renal disease. For example, mild thiazide diuretics have little diuretic effect in patients with severe CKD.

Renal elimination

The major problem in the use of drugs in CKD concerns the reduced elimination of many drugs normally excreted by the kidneys.

Water-soluble drugs such as gentamicin that are poorly absorbed from the gut, typically given by injection and not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver. Metabolites of lipid-soluble drugs, however, may themselves be water-soluble and potentially toxic.

Drugs causing uraemia by effects upon protein anabolism and catabolism

Tetracyclines, with the exception of doxycycline, have a catabolic effect and as a result the concentration of nitrogenous waste products is increased. They may also cause impairment of GFR by a direct effect. Corticosteroids have a catabolic effect and so also increase the production of nitrogenous wastes. A patient with moderate impairment of renal function may therefore become severely uraemic if given tetracyclines or corticosteroid therapy.

Drugs and toxic agents causing specific renal tubular syndromes include mercury, lead, cadmium and vitamin D.

Problem patients

Particular problems are presented by patients in whom renal function is altering rapidly, such as those with recovering acute tubular necrosis. In addition, drugs may be removed by dialysis and haemofiltration, which will affect the dosage required.

ACUTE KIDNEY INJURY (AKI)

Definition

Acute kidney injury has variably been defined as an abrupt deterioration in parenchymal renal function, which is usually, but not invariably, reversible over a period of days or weeks. In clinical practice, such deterioration in renal function is sufficiently severe to result in uraemia. Oliguria is usually, but not invariably, a feature. Acute kidney injury may cause sudden, life-threatening biochemical disturbances and is a medical emergency. The distinction between acute and CKD or even acute-on chronic kidney disease, cannot be readily apparent in a patient presenting with uraemia. In view of these difficulties, the Acute Dialysis Quality Initiative group proposed the RIFLE (Risk, Injury, Failure, Loss, End-stage renal disease; [Box 12.5](#)) criteria utilizing either increases in serum creatinine or decreases in urine output. It characterizes three levels of renal dysfunction (R, I, F) and two outcome measures (L, E). These criteria indicate an increasing degree of renal damage and have a predictive value for mortality.

The Acute Kidney Injury Network (AKIN) has proposed a modification of the RIFLE criteria. It now includes less severe AKI, a time constraint of 48 hours, and gives a correction for volume status before classification. 'R' in RIFLE is stage 1 (a serum creatinine of $\geq 26.4 \mu\text{mol/L}$, i.e. a 1.5-fold increase within 48 hours); stage 2 is 'I', i.e. a 2–3-fold increase in serum creatinine; and 'F' is stage 3, i.e. an increase in serum creatinine of $>300\%$ (equal to $\geq 354 \mu\text{mol/L}$). Urine output data are the same.

Epidemiology

The observed incidence of AKI is highly dependent upon the populations studied and the definition of AKI employed, e.g.:

- Community-acquired AKI on admission to hospital: approximately 1% in the UK (superimposed on CKD in half of these patients)
- Severe AKI (creatinine $>500 \mu\text{mol/L}$): about 130–140/million population per year
- Less severe AKI (creatinine levels of up to $177 \mu\text{mol/L}$ or a 50% rise from baseline): about 200/million/year.

The incidence of hospital-acquired AKI has increased.

The outcome of AKI also varies greatly. Uncomplicated AKI can usually be managed outside the intensive care unit (ITU) setting and carries a good prognosis, with mortality rates $<5\text{--}10\%$. In contrast, AKI complicating non-renal organ system failure (in the ITU setting) is associated with mortality rates of 50–70%, which have not changed for several decades. Sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.

Classification

Renal failure results in reduced excretion of nitrogenous waste products, of which urea is the most commonly measured. A raised serum urea concentration (uraemia) is classified as:

- pre-renal
- renal or
- post-renal.

More than one category may be present in an individual patient. Other causes of altered serum urea and creatinine concentration are shown in [Table 12.18](#).

Pre-renal uraemia

In pre-renal uraemia, there is impaired perfusion of the kidneys with blood. This results either from hypovolaemia, hypotension, impaired cardiac pump efficiency or vascular disease limiting renal blood flow, or combinations of these factors. Usually the kidney is able to maintain glomerular filtration close to normal despite wide variations in renal perfusion pressure and volume status – so-called 'autoregulation'. Further depression of renal perfusion leads to a drop in glomerular filtration and development of pre-renal uraemia. Drugs which impair renal autoregulation, such as ACE inhibitors and NSAIDs, increase the tendency to develop pre-renal uraemia.

All causes of pre-renal uraemia may lead to established parenchymal kidney damage and the development of AKI. By definition, excretory function in pre-renal uraemia improves once normal renal perfusion has been restored.

Acute kidney injury (AKI)

Box 12.5 RIFLE classification for acute kidney injury

Grade	GFR criteria	UO criteria
Risk	SCr $\times 1.5$ within 48 hr	UO $<0.5 \text{ mL/kg per h} \times 6 \text{ h}$
Injury	SCr $\times 2\text{--}3$	UO $<0.5 \text{ mL/kg per h} \times 12 \text{ h}$
Failure	SCr $\times 3$ or SCr $>350 \mu\text{mol/L}$ with an acute rise $>40 \mu\text{mol/L}$	UO $<0.3 \text{ mL/kg per h} \times 24 \text{ h}$
Loss	Persistent AKI >4 weeks	
ESKD	Persistent renal failure >3 months	

SCr, serum creatinine; UO, urinary output; ESKD, end-stage kidney disease; RIFLE, Risk, Injury, Failure, Loss, End-stage renal disease.

Table 12.18 Causes of altered serum urea and creatinine concentration other than altered renal function

	Decreased concentration	Increased concentration
Urea	Low protein intake Liver failure Sodium valproate treatment	Corticosteroid treatment Tetracycline treatment Gastrointestinal bleeding
Creatinine	Low muscle mass	High muscle mass Red meat ingestion Muscle damage (rhabdomyolysis) Decreased tubular secretion (e.g. cimetidine, trimethoprim therapy)

Table 12.19 Criteria for distinction between pre-renal and intrinsic causes of renal dysfunction

	Pre-renal	Intrinsic
Urine specific gravity	>1.020	<1.010
Urine osmolality (mOsm/kg)	>500	<350
Urine sodium (mmol/L)	<20	>40
$FE_{Na} = \frac{U_{Na}}{P_{Na}} + \frac{U_{Cr}}{P_{Cr}} \times 100$	<1%	>1%
FE, fractional excretion; P, plasma; U, urine; Cr, creatinine; Na, sodium.		

A number of criteria have been proposed to differentiate between pre-renal and intrinsic renal causes of uraemia (Table 12.19).

- **Urine specific gravity and urine osmolality** are easily obtained measures of concentrating ability but are unreliable in the presence of glycosuria or other osmotically active substances in the urine.
- **Urine sodium** is low if there is avid tubular reabsorption, but may be increased by diuretics or dopamine.
- **Fractional excretion of sodium (FE_{Na})** (Table 12.19), the ratio of sodium clearance to creatinine clearance, increases the reliability of this index but may remain low in some 'intrinsic' renal diseases, including contrast nephropathy and myoglobinuria.

Laboratory tests, however, are no substitute for clinical assessment. A history of blood or fluid loss, sepsis potentially leading to vasodilatation, or of cardiac disease may be helpful. Hypotension (especially postural), a weak rapid pulse and a low jugular venous pressure will suggest that the uraemia is pre-renal. In doubtful cases, measurement of central venous pressure is often invaluable, particularly with fluid challenge (see p. 873).

Management

If the pre-renal uraemia is a result of hypovolaemia and hypotension, prompt replacement with appropriate fluid is essential to correct the problem and prevent development of ischaemic renal injury and acute kidney disease (p. 885). Since pre-renal and renal uraemia may co-exist, and fluid challenge in the latter situation may lead to volume overload with pulmonary oedema, careful clinical monitoring is vital. Blood pressure should be checked regularly and signs of elevated jugular venous pressure and of pulmonary oedema sought frequently. Central venous pressure monitoring is usually advisable (see p. 872). If the problem relates to cardiac pump insufficiency or occlusion of the renal vasculature, appropriate measures – albeit often unsuccessful – need to be taken.

Post-renal uraemia

Here, uraemia results from obstruction of the urinary tract at any point from the calyces to the external urethral orifice. The causes and presentation of urinary tract obstruction are dealt with on page 604. Screening for urinary tract obstruction is by renal ultrasonography. Urinary tract obstruction may present in an acute fashion (if obstruction of a single functioning kidney by, e.g. a calculus occurs) but typically is of insidious onset.

Table 12.20 Some causes of acute tubular necrosis

Haemorrhage
Burns
Diarrhoea and vomiting, fluid loss from fistulae
Pancreatitis
Diuretics
Myocardial infarction
Congestive cardiac failure
Endotoxic shock
Snake bite
Myoglobinaemia
Haemoglobinaemia (due to haemolysis, e.g. in falciparum malaria, 'blackwater fever')
Hepatorenal syndrome
Radiological contrast agents (see p. 614)
Drugs, e.g. aminoglycosides, NSAIDs, ACE inhibitors, platinum derivatives
Abruptio placentae
Pre-eclampsia and eclampsia

Acute uraemia due to renal parenchymal disease

Causes

This is most commonly due to acute renal tubular necrosis (Table 12.20). Other causes include disease affecting the intrarenal arteries and arterioles as well as glomerular capillaries, such as a vasculitis (Chapter 11), accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura (TTP), Pre-eclampsia and crescentic glomerulonephritis. Acute tubulointerstitial nephritis (p. 595) may also cause AKI. This also occurs when renal tubules are acutely obstructed by crystals, for example following sulphonamide therapy in a dehydrated patient (sulphonamide crystalluria) or after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy). Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney can cause acute uraemia.

Acute tubular necrosis

Causes

Acute tubular necrosis (ATN) is common, particularly in hospital practice. It results most often from renal ischaemia but can also be caused by direct renal toxins including drugs such as the aminoglycosides, lithium and platinum derivatives (Table 12.20).

Kidneys are particularly vulnerable to ischaemic injury when cholestatic jaundice is present, and more than one ischaemic factor appears to be present in some situations. For example, disseminated intravascular coagulation complicating Gram-negative septicaemia and complications of pregnancy such as placental rupture, pre-eclampsia and eclampsia may result in occlusion or partial occlusion of intrarenal vessels, exacerbating the ischaemic insult resulting from hypotension associated with the underlying condition.

Myoglobinaemia and haemoglobinaemia consequent upon muscle injury (rhabdomyolysis) complicating trauma, pressure necrosis or heroin use predispose to ATN, perhaps in part owing to occlusion of renal tubules by myoglobin and haemoglobin casts. In liver failure, AKI appears to result from rapidly reversible vasomotor abnormalities within the kidney. A kidney removed from a patient with hepatic cirrhosis and liver failure dying with oliguric renal failure may function normally immediately after transplantation into a normal

Bosch X et al. Rhabdomyolysis and acute kidney disease. *N Engl J Med* 2009; 361:62–72.

individual. Efferent glomerular arteriolar dilatation resulting from ACE-inhibitor drug therapy, with consequent lowering of glomerular filtration pressure, may cause acute deterioration in excretory function if renal arterial disease is also present (see Fig. 12.48). The effect is compounded by concomitant use of non-steroidal anti-inflammatory agents which reduce prostaglandin production, opposing this effect.

Pathogenesis

Factors postulated to be involved in the development of ATN include:

- **Intrarenal microvascular vasoconstriction:**
 - Vasoconstriction is increased in response to endothelin, adenosine, thromboxane A_2 , leukotrienes and sympathetic nerve activity. However, endothelin antagonists failed to show any beneficial effect in the clinical setting.
 - Vasodilatation is impaired due to reduced sensitivity in response to:
 - Nitric oxide, prostaglandins (PGE_2), acetylcholine and bradykinin
 - Increased endothelial and vascular smooth muscle cell structural damage
 - Increased leucocyte-endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation. After success in the prevention of AKI in animal models, anti-ICAM (intercellular adhesion molecule) in the clinical setting failed to live up to its initial promise.
- **Tubular cell injury.** Ischaemic injury results in rapid depletion of intracellular ATP stores resulting in cell death either by necrosis or apoptosis, due to the following:
 - Entry of calcium into cells with an increase in cytosolic cell calcium concentration
 - Induction by hypoxia of inducible nitric oxide synthases with increased production of nitric oxide causing cell death
 - Increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
 - Activation of phospholipase A_2 with increased production of free fatty acids, particularly arachidonic acid, due to its action on the lipid layer of cell membranes
 - Cell injury resulting from reperfusion with blood after initial ischaemia causing excessive free radical generation
 - Tubular obstruction by desquamated viable or necrotic cells and casts
 - Loss of cell polarity, i.e. integrins located on the basolateral side of the cell are translocated to the apical surface, which when combined with other desquamated cells forms casts, with tubular obstruction and back leak of tubular fluid.
- **Tubular cellular recovery.** Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin-like growth factor 1, epidermal growth factor and hepatocyte growth factor, and their receptors are upregulated during the regenerative process after injury.

In established ATN, renal blood flow is much reduced, particularly blood flow to the renal cortex. Ischaemic tubular

Figure 12.44 Acute tubular necrosis showing effacement and loss of the proximal tubule brush border, patchy loss of tubular cells and focal areas of proximal tubule dilatation (arrow).

damage contributes to a reduction in glomerular filtration by a number of interrelated mechanisms:

- **Glomerular contraction** reducing the surface area available for filtration, due to reflex afferent arteriolar spasm mediated by increased solute delivery to the macula densa. Increased solute delivery is due to impaired sodium absorption in the proximal tubular cells because of loss of cell polarity with mislocalization of the Na^+/K^+ -ATPase and impaired tight junction integrity, resulting in decreased apical-to-basal transcellular sodium absorption.
- **'Back leak' of filtrate** in the proximal tubule owing to loss of function of the tubular cells.
- **Obstruction of the tubule** by debris shed from ischaemic tubular cells; these appear on renal biopsy as flat rather than the normal tall appearance (Fig. 12.44).

Course

The clinical course of AKI associated with ATN is variable depending on the severity and duration of the renal insult. Oliguria is common in the early stages: non-oliguric AKI is usually a result of a less severe renal insult. Recovery of renal function typically occurs after 7–21 days, although recovery is delayed by continuing sepsis. In the recovery phase, GFR may remain low while urine output increases, sometimes to many litres a day owing to defective tubular reabsorption of filtrate. The clinical course is variable and ATN may last for up to 6 weeks, even after a relatively short-lived initial insult. Eventually renal function usually returns to almost normal or to normal, although exceptions exist (e.g. in renal cortical necrosis, see below).

No treatment is, as yet, known which will reduce the duration of acute renal tubular necrosis once it has occurred. The use of intravenous mannitol, furosemide or 'renal-dose' dopamine is not supported by controlled trial evidence, and none of these treatments is without risk.

Clinical and biochemical features

These are the features of the causal condition together with features of rapidly progressive uraemia. The rate at which serum urea and creatinine concentrations increase is dependent upon the rate of tissue breakdown in the individual patient. This is increased in the presence of trauma, sepsis and following surgery. *Hyperkalaemia* is common, particularly following trauma to muscle and in haemolytic states. *Metabolic acidosis* is usual unless hydrogen ion loss by vomiting or aspiration of gastric contents is a feature. *Hyponatraemia* may

be present owing to water overload if patients have continued to drink in the face of oliguria, or if overenthusiastic fluid replacement with 5% glucose has been carried out. Pulmonary oedema owing to salt and water retention is not uncommon, particularly after inappropriate attempts to initiate a diuresis by infusion of 0.9% saline without adequate monitoring of the patient's volume status. Hypocalcaemia due to reduced renal production of 1,25-dihydroxycholecalciferol and hyperphosphataemia due to phosphate retention are common.

Symptoms of uraemia such as anorexia, nausea, vomiting and pruritus develop, followed by intellectual clouding, drowsiness, fits, coma and haemorrhagic episodes. Epistaxes and gastrointestinal haemorrhage are relatively common. Severe infection may have initiated the AKI or have complicated it owing to the impaired immune defences of the uraemic patient or ill-considered management, such as the insertion and retention of an unnecessary bladder catheter with complicating urinary tract infection and bacteraemia.

Investigation of the uraemic emergency

Investigations are aimed at defining whether the patient has acute or chronic uraemia, whether uraemia results from pre-renal, renal or post-renal factors, and establishing the cause.

Acute or chronic uraemia?

The distinction between acute and chronic uraemia depends in part on the history, duration of symptoms and previous urinalysis or measurements of renal function.

A rapid rate of change of serum urea and creatinine with time suggests an acute process. A normochromic, normocytic anaemia suggests chronic disease, but anaemia may complicate many of the diseases that cause AKI, owing to a combination of haemolysis, haemorrhage and deficient erythropoietin production.

Ultrasound assessment of renal echogenicity and size is helpful. Small kidneys of increased echogenicity are diagnostic of a chronic process, although the reverse is not true; the kidney may remain normal in size in diabetes and amyloidosis, for instance.

Evidence of renal osteodystrophy (e.g. digital subperiosteal erosions due to hyperparathyroid bone disease) is indicative of CKD.

Pre-renal, renal or post-renal uraemia?

Bladder outflow obstruction is ruled out by insertion of a urethral catheter or flushing of an existing catheter, which should then be removed unless a large volume of urine is obtained. Absence of upper tract dilatation on renal ultrasonography will, with very rare exceptions, rule out urinary tract obstruction.

The distinction between pre-renal and renal uraemia may be difficult (see p. 610). Assessment of the patient's volume status is essential and central venous pressure measurement is extremely helpful. If volume status is low, appropriate corrective measures are indicated. If no diuresis ensues, AKI is present.

Other investigations

- Urinalysis, urine microscopy, particularly for red cells and red-cell casts (indicative of glomerulonephritis) and urine culture. Urine should be tested for free haemoglobin and myoglobin, where appropriate.
- In AKI it takes 48–72 hours before creatinine rises in the plasma; by that time cell injury is well established and irreversible. Urinary and plasma biomarkers (e.g. kidney

injury molecule 1, neutrophil gelatinase associated lipocalin) rise within few hours of AKI and may allow earlier treatment.

- Blood tests include measurement of serum urea, electrolytes, creatinine, calcium, phosphate, albumin, alkaline phosphatase and urate concentrations, as well as full blood count and examination of the peripheral blood film where necessary. Coagulation studies, blood cultures and measurements of nephrotoxic drug blood levels should be carried out.

Management

The aim of management of acute renal tubular necrosis is to keep the patient alive until spontaneous recovery of renal function occurs. Ideally patients should be managed by a nephrologist or intensivist with access to facilities for blood purification and fluid removal (see below). Early specialist referral is advisable. Poor initial management and late referral result in the arrival in the specialist centre of a patient who is severely uraemic, acidotic and hyperkalaemic.

General measures

Good nursing and physiotherapy are vital. Regular oral toilet, chest physiotherapy and consistent documentation of fluid intake and output, and where possible measurement of daily bodyweight to assess fluid balance changes, all have a role. The patient should be confined to bed only if essential.

Emergency measures

Hyperkalemia

This is a life-threatening complication owing to the risk of cardiac dysrhythmias, particularly ventricular fibrillation. Treatment is outlined in Emergency Box 13.1.

Correction of acidosis with intravenous sodium bicarbonate will also reduce serum potassium concentration, but administration of sodium is inappropriate if the patient is salt and water overloaded. Rapid correction of acidosis in a hypocalcaemic patient may also trigger tetany, since hydrogen ions displace calcium from albumin-binding sites, thus increasing the physiologically active calcium concentration in blood. Ion exchange resins are used to prevent subsequent hyperkalaemia. In many patients, hyperkalaemia will be controlled only by dialysis or haemofiltration.

Pulmonary oedema

Unless a diuresis can be induced with intravenous furosemide, dialysis or haemofiltration will be required.

Sepsis

Infections, when detected, should be treated promptly, bearing in mind the need to avoid nephrotoxic drugs and to use drugs with appropriate monitoring and drug levels (e.g. gentamicin, vancomycin). Prophylactic antibiotics or barrier nursing is not recommended in all cases.

Use of drugs

Great care must be exercised in the use of drugs (see p. 607).

Fluid and electrolyte balance

Twice-daily clinical assessment is needed. In general, once the patient is euvolaemic, daily fluid intake should equal urine output plus losses from fistulae and from vomiting, plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance. Sodium and potassium intake should be minimized. If abnormal losses of

fluid occur, e.g. in diarrhoea, additional fluid and electrolytes will be required. The development of signs of salt and water overload (peripheral oedema, basal crackles, elevation of jugular venous pressure) or of hypovolaemia should prompt reappraisal of fluid intake. Large changes in daily weight reflecting change in fluid balance status should also prompt a reappraisal of volume stasis.

Diet

With rare exceptions, sodium and potassium restriction are appropriate. The place of dietary protein restriction is controversial. If it is hoped to avoid dialysis or haemofiltration, protein intake is sometimes restricted to approximately 40 g daily. This poses the risk of a negative nitrogen balance despite attempts to reduce endogenous protein catabolism by maintenance of a high energy intake in the form of carbohydrate and fat. Patients treated by blood purification techniques are more appropriately managed by providing 70 g protein daily or more. Hypercatabolic patients will require an even higher nitrogen intake to prevent negative nitrogen balance.

Routes of intake are, in preferred order, enteral by mouth, enteral by nasogastric tube, and parenteral. The last of these is, however, only necessary if vomiting or bowel dysfunction render the enteral route inappropriate.

Vitamin supplements are usually supplied. Vitamin D analogue therapy and pharmacological doses of erythropoietin are not employed routinely.

Dialysis and haemofiltration

The main indications for blood purification and/or excess fluid removal by these techniques are:

- Symptoms of uraemia
- Complications of uraemia, such as pericarditis
- Severe biochemical derangement in the absence of symptoms (especially if a rising trend is observed in an oliguric patient and in hypercatabolic patients)
- Hyperkalaemia not controlled by conservative measures
- Pulmonary oedema
- Severe acidosis
- For removal of drugs causing the AKI, e.g. gentamicin, lithium, severe aspirin overdose.

The main options are intermittent haemodialysis (HD) combined with ultrafiltration if necessary, intermittent haemofiltration, continuous arteriovenous or venovenous haemofiltration, haemodiafiltration and peritoneal dialysis. For reasons that are incompletely understood, adverse cardiovascular effects are much less during haemofiltration than during haemodialysis. Continuous treatments are superior to intermittent ones in this respect.

Continuous renal replacement treatments (CRRT)

Blood flow is achieved either by using the patient's own blood pressure to generate arterial blood flow through a filter or by the use of a blood pump to draw blood from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein.

Continuous arteriovenous or venovenous haemofiltration (CAVH, CVVH) refers to the continuous removal of ultrafiltrate from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient one might remove filtrate at 1000 mL/h and replace at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

Continuous haemodiafiltration (CAVHDF, CVVHDF) is a combination of haemofiltration and haemodialysis, involving both the net removal of ultrafiltrate from the blood and its replacement with a replacement solution, together with the countercurrent passage of dialysate (which may be identical to the replacement solution). Both the ultrafiltrate and the spent dialysate appear as 'waste'.

Comparisons of dialysis modalities

Peritoneal dialysis (PD) is used infrequently in the management of AKI. Drawbacks to the use of PD in AKI are:

- Low efficiency in fluid and solute removal compared to CRRT or intermittent HD
- AKI complicating intra-abdominal pathology is unsuitable for PD
- Increasing intraabdominal pressure can compromise lung function
- Use of dialysis fluids with a high glucose content may produce hyperglycaemia and other metabolic derangements. Data suggest that PD is significantly less effective than CRRT in the management of AKI and should be reserved for situations where other modalities of therapy are not available.

There are thus insufficient data to favour either HD or CRRT as a superior mode of therapy in AKI. However, there is consensus that in haemodynamically unstable patients, CRRT is better tolerated.

Membrane biocompatibility

The concept of membrane 'biocompatibility' relates to the activation of cellular (neutrophils, platelets) and humoral (complement system and coagulation cascade) components upon contact between blood and dialysis membranes. As a general rule, unsubstituted cellulose membranes (cuprophane) are the least biocompatible, with biocompatibility improving with substitution of free hydroxyl groups by tertiary amino groups (hemophan), acetate (cellulose acetate, diacetate, triacetate) or the use of synthetic polymers (e.g. polysulphone, polyamide, polyacrylonitrile and polymethylmethacrylate).

Synthetic membranes appear to confer a significant survival advantage over unsubstituted cellulose (cuprophane)-based membranes but no benefit on recovery of renal function.

Acute kidney injury in the intensive care unit (ICU) (see Chapter 16)

Increasing numbers of patients with AKI are managed in the setting of an intensive care unit. Many such patients have multiorgan failure, sepsis or both, with associated cardiovascular instability.

Fluids

The appropriate replacement fluid for plasma losses is 0.9% saline (e.g. burns, pancreatitis); 4% albumin or 0.9% saline is used for fluid resuscitation in ICU patients. There are no significant differences between them with respect to death rates, organ failure, the need for RRT or the duration of hospitalization. Serum K⁺ and acid-base status should be monitored in all subjects. K⁺ supplementation of replacement fluids should not be given unless there is hypokalaemia.

Fluid overload

Diuretics may be useful in volume overload in AKI. Non-oliguric patients with AKI fare better than oliguric patients. However, conversion of oliguria to non-oliguria has not been shown to decrease mortality. Diuretics have not been

FURTHER READING

Palevsky PM. Renal support in acute kidney injury – how much is enough? *N Engl J Med* 2009; 361:1699–1701.

shown to prevent AKI or improve outcomes in AKI. In fact, in AKI patients in the ICU, diuretic use is associated with a significant increase in the risk of death or non-recovery of renal function.

Nutrition

- Enteral feeding is the preferred means of nutritional supplementation.
- Protein and non-protein calories should be provided to meet calculated energy expenditures and at a protein intake not exceeding 1.5 g/kg per day.
- Total parenteral nutrition should be administered only to patients who are severely malnourished or patients expected to be unable to eat for >14 days.

Dialysis

Timing of initiation of dialysis is essentially an unresolved issue. However, there appears to be some evidence that early initiation of RRT (BUN levels of <76 mg/dL) may be associated with better outcomes. Continuous methods of blood purification and control of fluid balance, such as veno-venous haemofiltration, are preferable to intermittent haemodialysis or peritoneal dialysis in such patients. Advantages include:

- Much less disturbance of cardiovascular stability
- The ability to generate as much 'space' for fluid administration as is required, which can be adjusted flexibly to the needs of the patient (many patients require large volumes of fluid to be administered for nutritional and other reasons)
- The removal of potentially harmful substances such as inflammatory cytokines via the more porous membrane employed in haemofiltration.

Two large trials have failed to show a survival benefit of augmented doses of renal replacement therapy in critically ill patients. These essentially negative studies underscore the urgent need for strategies in the early detection and prevention of AKI.

Other interventions

Acute respiratory distress syndrome (ARDS) is not uncommon in patients with multiorgan failure, including acute kidney injury, requiring intensive therapy. In such patients the wish to remove as much fluid from the patient as possible to reduce pulmonary congestion must be balanced against the need of organs, including the kidneys, for an adequate blood flow, if recovery is to occur. Anaemia is relatively common in patients admitted to ITU and is managed by blood transfusions. In a study, erythropoietin (EPO) given weekly did not reduce the blood transfusion requirements but unexpectedly increased survival in trauma patients. This also showed that EPO has non-haemopoietic pleiotrophic effects by which it reduces the risk of acute ischaemia and reperfusion injury in multiple organs.

Management of the recovery phase

Usually, after 1–3 weeks, renal function improves, as evidenced by an increase in urine volume and improvement in serum biochemistry. Dialysis or haemofiltration, if they have been required, can be discontinued. A careful watch on clinical state, salt and water balance, and serum chemistry is required at this stage, particularly if a major diuretic phase develops owing to recovery of glomerular filtration at a time when renal tubular reabsorptive capacity for sodium, potassium and water remains impaired. Intravenous fluid replacement is sometimes required together with supplements of

sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

Acute cortical necrosis

Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible owing to the capacity of the tubular cells for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring – glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed 'cortical necrosis'. This may be patchy or complete. Any cause of acute tubular necrosis, if sufficiently severe or prolonged, may lead to cortical necrosis. This outcome is particularly common if acute kidney injury has been accompanied by derangements of the vascular endothelial system or coagulation system, such as occurs in the haemolytic uraemic syndrome and with complications of pregnancy.

Contrast nephropathy

In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasoconstriction and by a direct toxic effect upon renal tubules. The effect is dose-dependent and therefore more commonly seen in procedures that require large amounts of contrast media, such as angiography with or without angioplasty. In many patients, the effect is mild, transient, fully reversible and was thought of as benign and of no clinical significance. However, even transient elevation of creatinine following contrast administration particularly as part of coronary angiography is associated with long-term consequences such as increased risk of cardiac events, end-stage renal disease and mortality. The risk and severity of contrast nephropathy is amplified by the presence of hypovolaemia and severity of CKD, especially if due to diabetic nephropathy. Diabetes per se is not a risk factor. However, metformin can precipitate acidosis and should be stopped and not restarted until renal function returns to the baseline level.

Prevention involves minimization, as far as possible, of the dose of contrast employed and use of an iso-osmolar or low-osmolality contrast medium. Superiority of iso-osmolar agents has been questioned by randomized trials in patients with severe CKD (eGFR <30 mL/min) undergoing coronary angiogram, where no differences were seen between the two types of contrast agent. Pre-hydration with intravenous saline is of proven benefit. A popular regimen involves infusion of 1 L of 0.9% saline during the 12 h before and 12 h after contrast exposure. Administration of 1 L of sodium bicarbonate 1.4% peri-procedure and up to 8–12 h post-procedure has been shown to be more effective than saline in some studies. Care must be taken to avoid volume overload in susceptible patients.

Acetylcysteine (potent antioxidant) given 48 hours prior to radiological intervention may be of borderline benefit in preventing worsening of pre-existing CKD following intravenous contrast, but the beneficial effects on morbidity and mortality are not detected. Routine use of dopamine, theophylline (an adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from circulation) is of no benefit. In patients with advanced CKD who are undergoing coronary angiography, periprocedural haemofiltration given in an ITU setting appears to be effective in preventing the deterioration of renal function due to contrast agent-induced nephropathy and is associated with improved in-hospital and long-term outcomes.

When deterioration in renal function occurs after intra-arterial injection of contrast (e.g. after coronary angiography) it may be difficult to differentiate the effects of contrast-induced damage from those of atheromatous embolization (see p. 599). The latter carries a worse prognosis.

Note: Gadolinium used in contrast MRI causes problems in CKD (see p. 598).

Acute phosphate nephropathy (APN)

Administration of oral sodium phosphate solution as bowel preparation for gastrointestinal investigations has recently been recognized as a cause of AKI. Risk factors for the development of APN include CKD, dehydration, older age, hypertension treated with ACE inhibitors and or ARBs and or loop diuretics, female gender and NSAIDs. Oral phosphate solution is contraindicated in patients with CKD, congestive heart failure, gastrointestinal obstruction, and pre-existing electrolyte disorders like hypercalcaemia. The diagnosis of acute phosphate nephropathy is made by:

- AKI
- Recent exposure to oral phosphate
- Renal biopsy findings of acute and chronic tubular injury with abundant calcium phosphate deposits (usually involving more than 40 tubular lumina in a single biopsy),
- No evidence of hypercalcaemia
- No other significant pattern of kidney injury on renal biopsy.

Treatment is usually supportive and dialysis if necessary with good renal recovery.

Hepatorenal syndrome (HRS)

The renal failure observed in HRS results from profound renal vasoconstriction with histologically normal kidneys (p. 337). Although many of the features of HRS resemble pre-renal AKI, the defining feature is a lack of improvement in renal function with volume expansion. Renal recovery is usually observed after restoration of hepatic function after successful liver transplantation.

CHRONIC KIDNEY DISEASE (CKD)

The term 'CKD' has replaced terms such as chronic renal failure or insufficiency. CKD implies longstanding (more than 3 months), and usually progressive, impairment in renal function. In many instances, no effective means are available to reverse the primary disease process. Exceptions include correction of urinary tract obstruction, immunosuppressive therapy for systemic vasculitis and Goodpasture's syndrome, treatment of accelerated hypertension, and correction of critical narrowing of renal arteries causing CKD. The rate of deterioration in renal function can, however, be slowed (see p. 622). A list of causes of CKD is given in Table 12.21.

Wide geographical variations in the incidence of disorders causing CKD exist. The most common cause of glomerulonephritis in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of CKD due to urinary tract obstruction in parts of the Middle East, including southern Iraq. The incidence of ESKD varies between racial groups. ESKD is three to four times as common in black Africans in the UK and USA as it is in whites, and hypertensive nephropathy is a much more frequent cause of ESKD in this group. The prevalence

Table 12.21 Causes of chronic kidney disease

Congenital and inherited disease

Polycystic kidney disease (adult and infantile forms)
Medullary cystic disease
Tuberous sclerosis
Oxalosis
Cystinosis
Congenital obstructive uropathy

Glomerular disease

Primary glomerulonephritides including focal glomerulosclerosis
Secondary glomerular disease (systemic lupus, polyangiitis, Wegener's granulomatosis, amyloidosis, diabetic glomerulosclerosis, accelerated hypertension, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, systemic sclerosis, sickle cell disease)

Vascular disease

Hypertensive nephrosclerosis (common in black Africans)
Renovascular disease
Small and medium-sized vessel vasculitis

Tubulointerstitial disease

Tubulointerstitial nephritis – idiopathic, due to drugs (especially nephrotoxic analgesics), immunologically mediated
Reflux nephropathy
Tuberculosis
Schistosomiasis
Nephrocalcinosis
Multiple myeloma (myeloma kidney)
Balkan nephropathy
Renal papillary necrosis (diabetes, sickle cell disease and trait, analgesic nephropathy)
Chinese herb nephropathy

Urinary tract obstruction

Calculus disease
Prostatic disease
Pelvic tumours
Retroperitoneal fibrosis
Schistosomiasis

of diabetes mellitus and hence of diabetic nephropathy is higher in some Asian groups than in whites. The age is of relevance; CKD due to atherosclerotic renal vascular disease is much more common in the elderly than in the young. Over 70% of all cases with CKD are due to diabetes mellitus, hypertension and atherosclerosis.

Patients with CKD should be referred to a nephrologist with access to facilities for renal replacement therapy at an early stage since late referral has been shown to be associated with increased mortality and morbidity when such patients commence renal replacement therapy. Old age is no bar to referral in the reasonably fit elderly patient.

For CKD referral and treatment pathways, the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation established a classification of CKD in the USA in 2002, and endorsed by the Kidney Disease: Improving Global Outcomes (KDIGO) in 2004. According to KDIGO and KDOQI, the definition and classification should reflect patient prognosis and outcomes. KDIGO initiated a collaborative meta-analysis to examine the relationship of eGFR and albuminuria to mortality and kidney outcomes. It has been agreed by experts that:

- The current definition for CKD will be retained: GFR <60 mL/min per 1.73 m² or a urinary albumin-to-creatinine ratio >65 mg/mmol or protein creatinine ratio of 100 mg/mmol (Table 12.22)
- The classification has been modified by adding albuminuria stage, subdivision of stage 3 into A and B, and emphasizing clinical diagnosis.

Table 12.22 Classification of CKD

Stage	GFR (mL/min/1.73 m ²)	Description
1	≥90	Normal or increased glomerular filtration rate (GFR), with other evidence of kidney damage
2	60–89	Slight decrease in GFR with other evidence of kidney damage
3A 3B	45–59 30–44	Moderate decrease in GFR with or without other evidence of kidney damage
4	15–29	Severe decrease in GFR with or without other evidence of kidney damage
5	<15	Established renal failure

Note: The suffix 'P' can be applied to the stage of CKD if the patient has significant proteinuria, defined as a urinary albumin:creatinine ratio >65 mg/mmol or protein:creatinine ratio >100 mg/mmol.
Source: NICE Clinical guidance 73. Chronic kidney disease. 2011.

FURTHER READING

Levey AS, de Jong PE, Coresh J et al. The definition, classification, and prognosis of chronic kidney disease: a KDIGO Controversies Conference report. *Kidney Int* 2011; 80(1):17–28.

Tonelli M, Muntner P, Lloyd A et al. Using proteinuria and estimated glomerular filtration rate to classify risk in patients with chronic kidney disease: a cohort study. *Ann Intern Med* 2011; 154(1): 12–21.

Table 12.23 Prevalence of CKD (percentage of the population affected)

CKD stage	Age (years)			
	Under 65 (%)	65–74 (%)	75–84 (%)	≥85 (%)
3	1.4	15.4	29.4	30.9
4	0.04	0.4	1.3	2.4
5	0.03	0.2	0.1	0.1
Total	1.5	15.9	30.9	33.4

High prevalences of CKD have now been found in population-based surveys particularly in elderly patients (Table 12.23) using the MDRD method (p. 565) to estimate GFR. Adoption of albuminuria or proteinuria along with eGFR in the new proposed classification will, according to some estimates, reduce the prevalence of CKD stages 3 and 4 from 10–15% of total population to more realistic numbers of less than 5% and would in the process avoid unnecessary referrals.

Clinical approach to the patient with CKD or any other form of renal disease

History

Particular attention should be paid to:

- **Duration of symptoms**
- **Drug ingestion**, including non-steroidal anti-inflammatory agents, analgesic and other medications, and unorthodox treatments such as herbal remedies
- **Previous medical and surgical history**, e.g. previous chemotherapy, multisystem diseases such as SLE, malaria
- **Previous occasions** on which urinalysis or measurement of urea and creatinine might have been performed, e.g. pre-employment or insurance medical examinations, new patient checks
- **Family history** of renal disease.

Symptoms

The early stages of CKD are often completely asymptomatic, despite the accumulation of numerous metabolites. Serum urea and creatinine concentrations are measured in CKD, since methods for their determination are available and a rough correlation exists between urea and creatinine concentrations and symptoms. These substances are, however, in themselves not particularly toxic. The nature of the metabolites that are involved in the genesis of symptoms is unclear. Such metabolites must be products of protein catabolism (since dietary protein restriction may reverse symptoms associated with CKD) and many of them must be of relatively small molecular size (since haemodialysis employing membranes which allow through only relatively small molecules improves symptoms). Little else is known with certainty.

Symptoms are common when the serum urea concentration exceeds 40 mmol/L, but many patients develop uraemic symptoms at lower levels of serum urea. Symptoms include:

- Malaise, loss of energy
- Loss of appetite
- Insomnia
- Nocturia and polyuria due to impaired concentrating ability
- Itching
- Nausea, vomiting and diarrhoea
- Paraesthesiae due to polyneuropathy
- 'Restless legs' syndrome (overwhelming need to frequently alter position of lower limbs)
- Bone pain due to metabolic bone disease
- Paraesthesiae and tetany due to hypocalcaemia
- Symptoms due to salt and water retention – peripheral or pulmonary oedema
- Symptoms due to anaemia
- Amenorrhoea in women; erectile dysfunction in men.

In more advanced uraemia CKD stage 5, these symptoms become more severe and CNS symptoms are common:

- Mental slowing, clouding of consciousness and seizures
- Myoclonic twitching.

Severe depression of glomerular filtration can result in oliguria. This can occur with either acute kidney injury or in the terminal stages of CKD. However, even if the GFR is profoundly depressed, failure of tubular reabsorption may lead to very high urine volumes; the urine output is therefore not a useful guide to renal function.

Examination

There are few physical signs of uraemia per se. Findings include: short stature (in patients who have had CKD in childhood); pallor (due to anaemia); increased photosensitive pigmentation (which may make the patient look misleadingly healthy); brown discoloration of the nails; scratch marks due to uraemic pruritus; signs of fluid overload (p. 642); pericardial friction rub; flow murmurs (mitral regurgitation due to mitral annular calcification; aortic and pulmonary regurgitant murmurs due to volume overload); and glove and stocking peripheral sensory loss (rare).

The kidneys themselves are usually impalpable unless grossly enlarged as a result of polycystic disease, obstruction or tumour. Rectal and vaginal examination may disclose evidence of an underlying cause of CKD, particularly urinary obstruction, and should always be performed.

Figure 12.45 Symptoms and signs of chronic kidney disease. Oedema may be due to a combination of primary renal salt and water retention and heart failure.

In addition to these findings, there may be physical signs of any underlying disease which may have caused the CKD, for instance:

- Cutaneous vasculitic lesions in systemic vasculitides
- Retinopathy in diabetes and hypertensive retinopathy in hypertension
- Evidence of peripheral vascular disease and associated renal artery stenosis
- Evidence of spina bifida or other causes of neurogenic bladder.

An assessment of the central venous pressure, skin turgor, blood pressure both lying and standing and peripheral circulation should also be made. The major symptoms and signs of CKD are shown in Figure 12.45.

Investigations

The following investigations are common for all renal patients. This includes patients with glomerular or non-glomerular disease, renal involvement in systemic diseases, AKI and CKD, as renal symptoms and signs are nonspecific.

Urinalysis

- **Haematuria** may indicate glomerulonephritis, but other sources must be excluded. Haematuria should not be assumed to be due to the presence of an indwelling catheter.
- **Proteinuria**, if heavy, is strongly suggestive of glomerular disease. Urinary infection may also cause proteinuria. *Glycosuria* with normal blood glucose is common in CKD.
- **Urine culture**, including early-morning urine samples for TB.

Urine microscopy (see p. 569)

- **White cells** in the urine usually indicate active bacterial urinary infection, but this is an uncommon cause of

CKD; sterile pyuria suggests papillary necrosis or renal tuberculosis.

- **Eosinophilia** is strongly suggestive of allergic tubulointerstitial nephritis or cholesterol embolization.
- **Casts.** *Granular casts* are formed from abnormal cells within the tubular lumen, and indicate active renal disease. *Red-cell casts* are highly suggestive of glomerulonephritis.
- **Red cells in the urine** may be from anywhere between the glomerulus and the urethral meatus (Fig. 12.6).

Urine biochemistry

- **Measurements of urinary electrolytes** are unhelpful in CKD. The use of urinary sodium concentration in the distinction between pre-renal and intrinsic renal disease is discussed on page 576.
- **Urine osmolality** is a measure of concentrating ability. A low urine osmolality is normal in the presence of a high fluid intake but indicates renal disease when the kidney should be concentrating urine, such as in hypovolaemia or hypotension.
- **Urine electrophoresis and immunofixation** is necessary for the detection of light chains, which can be present without a detectable serum paraprotein.

Serum biochemistry

- Urea and creatinine.
- Calculation of eGFR.
- Electrophoresis and immunofixation for myeloma.
- Elevations of creatine kinase and a disproportionate elevation in serum creatinine and potassium compared with urea suggest rhabdomyolysis.

Haematology

- **Eosinophilia** suggests vasculitis, allergic tubulointerstitial nephritis, or cholesterol embolism.
- **Markedly raised viscosity** or ESR suggests myeloma or vasculitis.
- **Fragmented red cells and/or thrombocytopenia** suggest intravascular haemolysis due to accelerated hypertension, haemolytic uraemic syndrome or thrombotic thrombocytopenic purpura.
- **Tests for sickle cell disease** should be performed when relevant.

Immunology

- **Complement components** may be low in active renal disease due to SLE, mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis, and cryoglobulinaemia.
- **Autoantibody screening** is useful in detection of SLE (p. 537); scleroderma (p. 539); Wegener's granulomatosis and microscopic polyangiitis (p. 854); and Goodpasture's syndrome (p. 812).
- **Cryoglobulins** in unexplained glomerular disease, particularly mesangiocapillary glomerulonephritis.
- **Antibodies to streptococcal antigens** (antistreptolysin O titre (ASOT), anti-DNAse B) if post-streptococcal glomerulonephritis is possible.
- **Antibodies to hepatitis B and C** may point to polyarteritis or membranous nephropathy (hepatitis B) or to cryoglobulinaemic renal disease (hepatitis C).
- **Antibodies to HIV** raise the possibility of HIV-associated renal disease.

Radiological investigation

- **Ultrasound.** Every patient should undergo ultrasonography (for renal size and to exclude hydronephrosis), and plain abdominal radiography and CT (without contrast) to exclude low-density renal stones or nephrocalcinosis, which may be missed on ultrasound.
- **CT** is also useful for the diagnosis of retroperitoneal fibrosis and some other causes of urinary obstruction, and may also demonstrate cortical scarring.
- **MRI.** Magnetic resonance angiography in renovascular disease. For gadolinium used as contrast in CKD, see this chapter.

Renal biopsy (see p. 572)

This should be performed in every person with unexplained CKD and normal-sized kidneys, unless there are strong contraindications. If rapidly progressive glomerulonephritis is possible, this investigation must be performed within 24 h of presentation if at all possible.

Complications of chronic kidney disease

Anaemia

Several factors have been implicated:

- **Erythropoietin deficiency** (the most significant)
- **Bone marrow toxins** retained in CKD
- **Bone marrow fibrosis** secondary to hyperparathyroidism
- **Haematinic deficiency** – iron, vitamin B₁₂, folate
- **Increased red-cell destruction**
- **Abnormal red-cell membranes** causing increased osmotic fragility
- **Increased blood loss** – occult gastrointestinal bleeding, blood sampling, blood loss during haemodialysis or because of platelet dysfunction
- **ACE inhibitors** (may cause anaemia in CKD, probably by interfering with the control of endogenous erythropoietin release).

Red-cell survival is reduced in CKD. Increased red-cell destruction may occur during haemodialysis owing to mechanical, oxidant and thermal damage.

Bone disease: renal osteodystrophy

The term 'renal osteodystrophy', more appropriately described as bone mineral disorder, embraces the various forms of bone disease that may develop alone or in combination in CKD – hyperparathyroid bone disease, osteomalacia, osteoporosis, osteosclerosis and adynamic bone disease (Fig. 12.46). Most patients with CKD are found, histologically, to have mixed bone disease. Covert renal osteodystrophy is present in many patients with moderate CKD and in almost all of those with ESKD.

Pathogenesis of bone disease

Phosphate retention owing to reduced excretion by the kidneys occurs in the very early stages of CKD. This results in the release of fibroblast growth factor 23 (FGF 23) and other phosphaturic agents by osteoblasts as a compensatory mechanism. FGF 23 causes phosphaturia to bring the plasma phosphate level to within the normal range. FGF 23 also downregulates 1 α -hydroxylase in an attempt to reduce intestinal absorption of phosphate. However, consistently elevated levels of FGF 23 after a while cannot control phosphate

Figure 12.46 Renal osteodystrophy: pathogenesis and radiological features of renal bone disease. ALP, alkaline phosphatase.

levels and its effects are overwhelmed by development of secondary hyperparathyroidism. Elevated FGF 23 levels are the strongest independent predictor of mortality in patients with CKD. This underscores the necessity of controlling phosphate levels during very early stages of CKD.

- Decreased renal production of the 1 α -hydroxylase enzyme results in reduced conversion of 25-(OH)₂D₃ to the more metabolically active 1,25-(OH)₂D₃.
- Reduced activation of vitamin D receptors (VDR) in the parathyroid glands leads to increased release of parathyroid hormone (*secondary hyperparathyroidism*).
- The calcium sensing receptors (CaR), expressed in the parathyroid glands, react rapidly to acute changes in extracellular calcium concentrations and a low calcium also leads to increased release of PTH.
- 1,25-Dihydroxycholecalciferol deficiency also results in gut calcium malabsorption.
- Phosphate retention owing to reduced excretion by the kidneys, also indirectly by lowering ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), results in an increase in PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium, and this opposes the tendency to develop hypocalcaemia induced by 1,25-(OH)₂D₃ deficiency and phosphate retention. This 'secondary' hyperparathyroidism leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica).

Radiologically, digital subperiosteal erosions and 'pepper-pot skull' are seen. Longstanding *secondary hyperparathyroidism* ultimately leads to hyperplasia of the glands with autonomous or *tertiary hyperparathyroidism* in which hypercalcaemia is present. Serum alkaline phosphatase concentration is raised in both secondary and tertiary hyperparathyroidism. Longstanding parathyroid hormone excess is also thought to cause increased bone density (osteosclerosis) seen particularly in the spine where alternating bands of sclerotic and porotic bone give rise to a characteristic 'rugger jersey' appearance on X-ray.

1,25-(OH)₂D₃ deficiency and hypocalcaemia result in impaired mineralization of osteoid (osteomalacia). Such impaired mineralization also occurs when osteoblasts are inhibited by, e.g. aluminium given as gut phosphorus binders, or accumulated in bone as a result of exposure to aluminium in source water used to make up dialysate for haemodialysis. In this situation, serum alkaline phosphatase concentration tends to be low or normal.

The condition of 'adynamic bone disease' in which both bone formation and resorption are depressed (in the absence of aluminium bone disease or overtreatment with vitamin D) is also seen. The pathogenesis of this condition is unclear and it is not known whether it leads to an increased risk of fractures or other complications. There may be hypercalcaemia; the serum alkaline phosphatase is normal, the PTH is low. X-rays and dual X-ray absorptiometry (DXA) scan show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with yearly DXA scan.

Management is discussed on [page 555](#).

Skin disease

Pruritus (itching) is common in severe CKD and is mainly due to retention of nitrogenous waste products of protein catabolism as it improves following dialysis. Other causes of pruritus include hypercalcaemia, hyperphosphataemia, elevated calcium×phosphate product, hyperparathyroidism (even if calcium and phosphate levels are normal) and iron deficiency.

In dialysis patients, inadequate dialysis is usually the cause of pruritus. Nevertheless, a significant number of dialysis patients who are well dialysed and in whom other causes of pruritus can be excluded suffer persistent itching. The cause is unknown and no effective treatment exists.

Many patients with CKD suffer from dry skin for which simple aqueous creams are helpful. Eczematous lesions, particularly in relation to the region of an arteriovenous fistula, are relatively common. CKD may also cause porphyria cutanea tarda (PCT), a blistering photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with a decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition similar to PCT but without enzyme deficiency, is also seen in CKD with increased frequency.

Nephrogenic systemic fibrosis (NSF)

NSF is a systemic fibrosing disorder with predominant skin involvement. It is seen only in patients with moderate to severe CKD (eGFR <30 mL/min), particularly patients on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in the causation of over 95% cases of NSF (see [p. 1220](#)).

The *diagnosis* is based upon a biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

NSF usually follows a chronic and unremitting course, with 30% having no improvement, 20% having modest improvement and 30% dying. No single therapy or combination of therapies has shown consistent benefit in NSF with exception of improvement in renal function. Improvement in the NSF may follow renal transplantation. *Prevention* is by avoiding the use of gadolinium-based contrast agents in patients with severe CKD (eGFR <30 mL/min) or those on dialysis therapy.

Gastrointestinal complications

These include decreased gastric emptying and increased risk of reflux oesophagitis, peptic ulceration, acute pancreatitis and constipation, particularly in patients on continuous ambulatory peritoneal dialysis (CAPD).

Elevations of serum amylase of up to three times normal may be found in CKD without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

Metabolic abnormalities

Gout. Urate retention is a common feature of CKD. Treatment of clinical gout is complicated by the nephrotoxic potential of NSAIDs. Colchicine is useful for the acute attack, and allopurinol should be introduced under colchicine cover to prevent further attacks. The dose of allopurinol should be reduced in CKD, e.g. 100 mg on alternate days.

Insulin. Insulin is catabolized by and to some extent excreted via the kidneys. For this reason, insulin requirements in diabetic patients decrease as CKD progresses. By contrast, end-organ resistance to insulin is a feature of advanced CKD resulting in modestly impaired glucose tolerance. Insulin resistance may contribute to hypertension and lipid abnormalities.

Lipid metabolism abnormalities. These are common in CKD, and include:

- Impaired clearance of triglyceride-rich particles
- Hypercholesterolaemia (particularly in advanced CKD).

The situation is further complicated in ESKD, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities. Correction of lipid abnormalities by, e.g. HMG-CoA reductase inhibitor therapy (statins), is used in patients with CKD, although without formal proof of survival benefit.

Endocrine abnormalities

These include:

- Hyperprolactinaemia, which may present with galactorrhoea in men as well as women
- Increased luteinizing hormone (LH) levels in both sexes, and abnormal pulsatility of LH release
- Decreased serum testosterone levels (only seldom below the normal level). Erectile dysfunction and decreased spermatogenesis are common
- Absence of normal cyclical changes in female sex hormones, resulting in oligomenorrhoea or amenorrhoea
- Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used)
- Abnormal thyroid hormone levels, partly because of altered protein binding. Measurement of thyroid-stimulating hormone (TSH) is the best way to assess

thyroid function. True hypothyroidism occurs with increased frequency in CKD.

Posterior pituitary gland function is normal in CKD.

Muscle dysfunction

Uraemia appears to interfere with muscle energy metabolism, but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

Nervous system

Central nervous system

Severe uraemia causes an unusual combination of depressed cerebral function and decreased seizure threshold. However, convulsions in a uraemic patient are much more commonly due to other causes such as accelerated hypertension, thrombotic thrombocytopenic purpura or drug accumulation. Asterix, tremor and myoclonus are also features of severe uraemia.

Rapid correction of severe uraemia by haemodialysis leads to *dialysis disequilibrium* owing to osmotic cerebral swelling. This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

'Dialysis dementia' is a syndrome of progressive intellectual deterioration, speech disturbance, myoclonus and fits, which is due to aluminium intoxication; it may be accompanied by aluminium bone disease and by microcytic anaemia. Low-grade aluminium exposure may also cause more subtle, subclinical deterioration in intellectual function. Prevention involves removal of aluminium from source water used to manufacture dialysis fluid, and restriction or avoidance of aluminium-containing gut phosphorus binders. Treatment is with the chelating agent desferrioxamine.

Psychiatric problems are common. Patients can have anxiety, depression, phobias and psychoses.

Autonomic nervous system

Increased circulating catecholamine levels associated with downregulation of α -receptors, impaired baroreceptor sensitivity and impaired efferent vagal function are common in CKD.

Overactivity of the sympathetic nervous system in CKD is believed to play a part in the genesis of hypertension in this condition. All of these abnormalities improve to some extent after institution of regular dialysis and resolve after successful renal transplantation.

Peripheral nervous system

- **Median nerve compression** in the carpal tunnel is common, usually due to β_2 -microglobulin-related amyloidosis. This can be avoided by haemofiltration and haemodiafiltration.
- **'Restless legs' syndrome** (p. 620) is common in uraemia. The syndrome is difficult to treat. Iron deficiency should be treated if present. Attention should be paid to adequacy of dialysis. Symptoms may improve with the correction of anaemia by erythropoietin. Clonazepam is sometimes useful. Renal transplantation cures the problem.
- **A polyneuropathy** occurs in patients who are inadequately dialysed.

Calciphylaxis

Also known as calcific uraemic arteriopathy, this is a rare but serious life-threatening complication in CKD patients. It is increasingly recognized as a contributing factor to death

Figure 12.47 Calciphylaxis: characteristic arterial calcification of the skin microvasculature in the absence of vasculitic change (arrow).

in dialysis patients. Aetiological factors include reduced serum levels of a calcification inhibitory protein (fetuin-A) and abnormalities in smooth muscle cell biology in uraemia. It presents as painful non-healing eschars with panniculitis and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small vessel thrombosis (Fig. 12.47).

Hyperparathyroidism and elevated concentrations of serum phosphate, morbid obesity and warfarin use remain consistent clinical features of most cases reported. Control of hyperparathyroidism is with either surgical intervention or with a calcimimetic agent.

Promising treatment options include hyperbaric oxygen therapy and sodium thiosulfate infusion. Benefits from bisphosphonates and tissue plasminogen activator have also been reported.

Cardiovascular disease

Life expectancy remains severely reduced compared with the normal population owing to a greatly increased (16-fold) incidence of cardiovascular disease, particularly myocardial infarction, cardiac failure, sudden cardiac death and stroke.

Risk factors

Hypertension is a frequent complication of CKD. Diabetes mellitus is the commonest cause of CKD. Dyslipidaemia is universal in uraemic patients. Furthermore, smoking is as common as in the general population and male gender is over-represented in patients with CKD. Ventricular hypertrophy is common, as is systolic and diastolic dysfunction. Diastolic dysfunction is largely attributable to left ventricular hypertrophy and contributes to hypotension during fluid removal on haemodialysis. Systolic dysfunction may be due to:

- Myocardial fibrosis
- Abnormal myocyte function owing to uraemia
- Calcium overload and hyperparathyroidism
- Carnitine and selenium deficiency.

Left ventricular hypertrophy is a risk factor for early death in CKD, as in the general population. Systolic dysfunction is also a marker for early death.

Coronary artery calcification. Traditional risk factors (e.g. smoking, diabetes) can only partly explain the risk in patients with chronic nephropathies.

Coronary artery calcification is more common in patients with ESKD than in normal individuals and it is highly likely that this contributes significantly to cardiovascular mortality. Vascular calcification is frequent in all sizes of vessel in CKD.

In addition to the classical risk factors for atherosclerosis:

- **A raised (calcium \times phosphate) product** causes medial calcification.

- **Hyperparathyroidism** may also contribute independently to the pathogenesis by increasing intracellular calcium.
- **Vascular calcification** in uraemia is now thought to be an active process whereby vascular smooth muscle cells acquire osteoblast-like characteristics, possibly in response to elevated phosphate or (calcium \times phosphate) product.
- **Inflammation** is a potent mediator of vascular calcification by inhibition of fetuin (a glycoprotein synthesized by liver, which is a potent inhibitor of vascular calcification).

The impact of vascular calcification is the *reduction of vascular compliance*, which manifests by increased pulse pressure and pulse wave velocity, and increased afterload contributes further to left ventricular hypertrophy. In addition to myocardial abnormalities, vascular calcification with its associated biomechanical vessel wall alterations is a strong predictor of all-cause and cardiovascular morbidity and mortality in patients with CKD. Diffuse calcification of the myocardium is also common; the causes are similar.

Other cardiovascular risk factors. These include hyperhomocysteinaemia, *Chlamydia pneumoniae* infection, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) levels. High ADMA levels in uraemia are in part caused by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality. However, recent trials to reduce levels of homocysteine with folic acid, B₆ and B₁₂ supplementation have been unsuccessful.

The conclusion from a recent study of heart and renal protection (SHARP) in over 9500 CKD patients was that around one-quarter of all heart attacks, strokes, and revascularizations could be avoided in CKD by using a combination of ezetimibe and simvastatin to lower blood cholesterol. This combination however did not confer any survival advantage or prevent the development of ESKD.

Pericarditis

This is common and occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of underdialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should

be used with caution. Pericarditis usually resolves with intensive dialysis.

- Dialysis pericarditis occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

Malignancy

The incidence of malignancy is raised in patients with CKD and with dialysis. Malignant change can occur in multicystic kidney disease. Lymphomas, primary liver cancer and thyroid cancers also occur.

Management

Successful renal transplantation improves some, but not all, of the complications of CKD, therefore attempts should be made to prevent these complications by careful monitoring with ECG, echocardiography, angiography (if necessary) and nuclear imaging. CT (spiral CT) and/or MRI are useful in the assessment of arterial calcification. Treatment is with the control of risk factors (p. 608) as well as the treatment of hypercalcaemia and hyperparathyroidism (p. 624).

Progression of chronic kidney disease

CKD tends to progress inexorably to ESKD, although the rate of progression may depend upon the underlying nephropathy. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Hypertension and heavy proteinuria are bad prognostic indicators. A nonspecific renal scarring process common to renal disorders of different aetiologies may be responsible for progression.

Possible causes of glomerular scarring and proteinuria include:

- A rise in intraglomerular capillary pressure
- Adaptive glomerular hypertrophy due to reduced arteriolar resistance and increased glomerular blood flow when there is reduced nephron mass.

This glomerular hyperfiltration, in response to nephron loss, was postulated as a common pathway for the progression of CKD.

Since the afferent arteriolar tone decreases more than efferent arteriolar tone, intraglomerular pressure and the amount of filtrate formed by a single nephron rises. Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, predominantly causing vasoconstriction of postglomerular arterioles, thereby increasing the glomerular hydraulic pressure and filtration fraction (Fig. 12.48). In

Figure 12.48 Glomerular dynamics: effect of the renin-angiotensin system. AI, angiotensin I; AII, angiotensin II.

Box 12.6 Renoprotection

Goals of treatment

- BP <120/80
- Proteinuria <0.3 g/24 h

Treatment

Patients with chronic kidney disease and proteinuria >1 g/24 h:

- ACE inhibitor increasing to maximum dose
- Add angiotensin receptor antagonist if goals are not achieved^a
- Add diuretic to prevent hyperkalaemia and help to control BP
- Add calcium-channel blocker (verapamil or diltiazem) if goals not achieved

Additional measures

- Statins to lower cholesterol to <4.5 mmol/L
- Stop smoking (three-fold higher rate of deterioration in CKD)
- Treat diabetes (HbA_{1c} <7%, 53 mmol/mol)
- Normal protein diet (0.8–1 g/kg bodyweight)

^aIn type 2 diabetes start with angiotensin receptor antagonist.

addition, by its effect on mesangial cells and podocytes, it increases the pore sizes and impairs the size-selective function of basement membrane for macromolecules.

Angiotensin II also modulates cell growth directly and indirectly by upregulating TGF- β , a potent fibrogenic cytokine, increases collagen synthesis and also causes epithelial cell transdifferentiation to myofibroblasts which contribute to excessive matrix formation. Furthermore, angiotensin II by upregulating plasminogen activator inhibitor-1 (PAI-1) inhibits matrix proteolysis by plasmin, resulting in accumulation of excessive matrix and scarring both in the glomeruli and interstitium.

Renal interstitial scarring is also a factor. The cause of this progressive interstitial damage and fibrosis is multifactorial. In addition to non-haemodynamic effects of angiotensin II, proteinuria *per se* (by exposing tubular cells to albumin and its bound fatty acids and cytokines) promotes secretion of pro-inflammatory mediators, which promote interstitial inflammatory cell infiltrate and further augment fibrosis and progression of CKD. The prognosis for renal function in chronic glomerular disorders is judged more accurately by interstitial histological appearances than by glomerular morphology.

Therapeutic manoeuvres (Box 12.6) aimed at inhibiting angiotensin II and reducing proteinuria mainly by ACEI and angiotensin-receptor antagonists have beneficial effects in slowing the rate of progression of CKD in both diabetic and non-diabetic renal diseases in humans.

Management of chronic kidney disease

The underlying cause of CKD should be treated aggressively wherever possible.

Renoprotection

The multidrug approach to chronic nephropathies has been formalized in an international protocol (Box 12.6).

Correction of complications

Hyperkalaemia

Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs which cause potassium retention (see

p. 655) should be stopped. Occasionally, it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Emergency treatment of severe hyperkalaemia is described on page 655.

Acidosis

Correction of acidosis helps to correct hyperkalaemia in CKD, and may also decrease muscle catabolism. Sodium bicarbonate supplements are often effective (4.8 g (57 mmol) of Na⁺ and HCO₃⁻ daily), and the possibility of oedema and hypertension owing to the so-called 'extracellular fluid expansion' was not borne out by a trial. Interestingly, correction of metabolic acidosis by sodium bicarbonate at a mean dose of 1.8 g/day was also associated with marked reduction in the rate of progression of CKD and development of ESKD in patients with stage 4 and 5 CKD. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

Calcium and phosphate control and suppression of PTH

Hypocalcaemia and hyperphosphataemia should be treated aggressively, preferably with regular (e.g. 3-monthly) measurements of serum PTH to assess how effectively hyperparathyroidism is being suppressed. Suppression of PTH levels to below two or three times the upper limit of 'normal' carries a high risk of development of a dynamic bone disease.

Dietary restriction of phosphate is seldom effective alone, because so many foods contain it. Oral calcium carbonate or acetate reduces absorption of dietary phosphate but is contraindicated where there is hypercalcaemia or hypercalciuria. Aluminium-containing gut phosphate binders are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are now rarely used in the developed countries but are still used in the developing countries because they are extremely cheap.

Treatment

- **Gut phosphate binders.** The polymer sevelamer reduces the calcium load and attenuates vascular calcification and also lowers cholesterol levels by 10%. However, it has not been shown to reduce mortality. Lanthanum carbonate is a non-calcium, non-aluminium phosphate binder that is effective and has a good safety profile.
- **Nicotinamide**, an alternative to phosphate binders, blocks the intestinal sodium/inorganic phosphate (Na/Pi) cotransporter. It reduces phosphate levels and PTH levels alongside improvement in the lipid profile in dialysis patients.
- **Calcitriol (1,25-dihydroxycholecalciferol) or a vitamin D analogue**, such as alfacalcidol, used in early CKD has no deleterious effect upon renal function provided hypercalcaemia is avoided. New vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol) are less calcaemic. However, with the exception of paricalcitol (19-nor-1,25 dihydroxyvitamin D₂, which may have survival advantage), their usefulness over conventional but less expensive calcitriol or alfacalcidol remains to be established. Treatment with vitamin D analogues should be started only if serum PTH level is three times or more above the upper limit of normal, in order to prevent the development of a dynamic bone disease (see p. 619). Vitamin D therapy has the disadvantage that it increases not only calcium but also phosphate absorption and

may therefore exacerbate hyperphosphataemia and ectopic calcification including calciphylaxis (calcification of small vessels).

- **Calcimimetic agents** (e.g. cinacalcet, a calcium-sensing receptor agonist, see p. 621) have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium \times phosphate product. The long-term safety and efficacy of these agents has recently been confirmed and several observational studies have demonstrated that use of cinacalcet is associated with survival advantage.

Drug therapy

This should be minimized in patients with CKD. Tetracyclines (with the possible exception of doxycycline) should be avoided in view of their anti-anabolic effect and tendency to worsen uraemia. Drugs excreted by the kidneys, such as gentamicin, should be prescribed only in the absence of any alternative and drug levels monitored if feasible. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided. Potassium-sparing agents, such as spironolactone and amiloride, pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Bardoxolone, an antioxidant inflammatory modulator, has shown a reduction in GFR in diabetic CKD.

Anaemia

The anaemia of erythropoietin (EPO) deficiency can be treated with synthetic (recombinant) human EPO (epoetin- α or - β , or the longer-acting darbepoetin- α or polyethylene glycol-bound epoetin- β). The intravenous route is used, initially with 50 U/kg of epoetin- α over 1–5 min, three times weekly. Subcutaneous administration of epoetin- α can also be used (see below). Blood pressure, haemoglobin concentration and reticulocyte count are measured every 2 weeks and the dose adjusted to maintain a target haemoglobin of 110–120 g/L. Darbepoetin- α can be used once a week. Continuous erythropoiesis receptor activator (CERA), a recently licensed epoetin in Europe, is a pegylated epoetin- β and can be given once a month. In trials, CERA has a similar activity to other types of epoetin. However, CERA use is extremely limited and data about loss of flexibility of dosing, overshooting the target haemoglobin and its efficacy in combination with short-acting epoetin are required before its widespread use.

The target haemoglobin to be achieved during the treatment of anaemia is being revised to between 110 and 120 g/L as studies in pre-dialysis CKD patients have not revealed any outcome benefits in patients who were treated to achieve higher haemoglobin targets (>120 g/L).

Failure to respond to 300 U/kg weekly, or a fall in haemoglobin after a satisfactory response, may be due to iron deficiency, bleeding, malignancy, infection, inflammation or formation of anti-EPO neutralizing antibodies. The demand for iron by the bone marrow is enormous when erythropoietin is commenced. Patients on EPO therapy are regularly monitored for iron status and considered iron deficient if plasma ferritin is <100 μ g/L, hypochromic RBCs >10%, transferrin saturation <20%. Functional iron deficiency due to poor mobilization of iron, despite adequate iron stores (ferritin >500 μ g/L) and a transferrin saturation of >20%, is a common finding in patients with chronic inflammation. It is caused by hepcidin (see p. 377), an acute phase reactant produced by the liver in response to cytokines, particularly IL-6. Intravenous (rather than oral) iron supplements optimize response

to EPO treatment by repletion of iron stores. A recent randomized trial has demonstrated a beneficial effect of i.v. iron even in patients with ferritin >800 μ g/L and transferrin saturation of 20%.

Correction of anaemia with EPO improves quality of life, exercise tolerance and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. Avoidance of blood transfusion also reduces the chance of sensitization to HLA antigens, which may otherwise be a barrier to successful renal transplantation.

The *disadvantages of erythropoietin therapy* are that it is expensive and causes a rise in blood pressure in up to 30% of patients, particularly in the first 6 months. Peripheral resistance rises in all patients, owing to loss of hypoxic vasodilatation and to increased blood viscosity. A rare complication is encephalopathy with fits, transient cortical blindness and hypertension. Several reports of anti-EPO antibody-mediated pure red-cell aplasia in patients receiving subcutaneous EPO therapy (particularly EPO- α) have been described. The exact cause is unknown but interventions such as using the intravenous route and changes in manufacture of prefilled syringes have reduced the number of cases by 80%. Other causes of anaemia should be looked for and treated appropriately (see p. 375).

Several erythropoiesis-stimulating agents are in clinical trials. An EPO mimetic is an engineered peptide which stimulates EPO receptor but still has to be given by injection. Oral agents which inhibit prolyl hydroxylase and prolong the life of HIF (hypoxia inducible factors) 1 α , a transcription factor for endogenous production of EPO, have shown promise in phase 2 trials.

Male erectile dysfunction

Testosterone deficiency should be corrected. The oral phosphodiesterase inhibitors, e.g. sildenafil, tadalafil and vardenafil, are effective in ESKD and are the first-line therapy. The use of nitrates is a contraindication to this treatment. Other treatments are discussed on page 966.

Early referral of patients with chronic kidney disease

Patients need time to adjust to the demands of CKD and its treatment, and to absorb information. Veins required in the future for fashioning of an arteriovenous fistula should not be rendered useless by cannulation (Fig. 12.49).

Figure 12.49 Intravenous cannula in exactly the **WRONG** place, in a right-handed patient with CKD who will in future need a left (non-dominant arm) radiocephalic fistula.

Zoccali C. Traditional and emerging cardiovascular and renal risk factors: an epidemiologic perspective. *Kidney Int* 2006; 70:26–33.

If the patient opts for regular haemodialysis, fashioning of an arteriovenous fistula should be carried out well in advance of the need for dialysis, when serum creatinine is of the order 400–500 μm in non-diabetics and at an even earlier stage in diabetics with poorer vasculature. Such fistulae require several weeks to mature and become usable for vascular access.

Renal replacement therapy

Approximately 100 white individuals per million population commence renal replacement therapy in the UK each year. The corresponding figure in black Africans and Asians in the UK is three to four times higher, largely owing to diabetic and hypertensive nephropathy. The aim of all renal replacement techniques is to mimic the excretory functions of the normal kidney, including excretion of nitrogenous wastes, maintenance of normal electrolyte concentrations, and maintenance of a normal extracellular volume.

Haemodialysis**Basic principles**

In haemodialysis, blood from the patient is pumped through an array of semipermeable membranes (the dialyser, often called an 'artificial kidney'), which bring the blood into close contact with dialysate, flowing countercurrent to the blood. The plasma biochemistry changes towards that of the dialysate owing to diffusion of molecules down their concentration gradients (Fig. 12.50).

The dialysis machine comprises a series of blood pumps, with pressure monitors and bubble detectors and a proportionating unit, also with pressure monitors and blood leak detectors. Blood flow during dialysis is usually 200–300 mL/min and the dialysate flow usually 500 mL/min. The efficiency of dialysis in achieving biochemical change depends on blood and dialysate flow and the surface area of the dialysis membrane.

Dialysate is prepared by a proportionating unit, which mixes specially purified water with concentrate, resulting in fluid with the composition described in Table 12.24.

Figure 12.50 Changes across a semipermeable dialysis membrane.

Table 12.24 Range of concentrations (mmol/L) in routinely available final dialysates used for haemodialysis

Sodium	130–145
Potassium	0.0–4.0
Calcium	1.0–1.6
Magnesium	0.25–0.85
Chloride	99–108
Bicarbonate	35–40
Glucose	0–10

Access for haemodialysis

Adequate dialysis requires a blood flow of at least 200 mL/min. The most reliable long-term way of achieving this is surgical construction of an arteriovenous fistula (Fig. 12.51), using the radial or brachial artery and the cephalic vein. This results in distension of the vein and thickening ('arterialization') of its wall, so that after 6–8 weeks large-bore needles may be inserted to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus), arteriovenous polytetrafluoroethylene (PTFE) grafts are used for access. However, these grafts have a very high incidence of thrombosis and 2-year graft patency is only 50–60%. Dipyridamole or fish oils improve graft patency but warfarin, aspirin and clopidogrel do not and are associated with a high incidence of complications. In patients with PTFE stenosis, balloon angioplasty followed by stenting is associated with better long-term patency rates compared with angioplasty alone.

If dialysis is needed immediately, a large-bore double lumen cannula may be inserted into a central vein – usually the subclavian, jugular or femoral. *Semipermanent dual-lumen venous catheters* can also be used, usually inserted via a skin tunnel to lessen the risk of infection. Stenosis of the subclavian vein is common, and the jugular route is preferred. However, they are associated with particularly high rates of infection, hospitalization, and death. These catheters are prone to partial or total occlusion, which may lead to inadequate dialysis and missed dialysis sessions and should be avoided whenever possible.

In a recent study a simple regimen in which recombinant tissue plasminogen activator (rt-PA) was used for locking the dialysis catheter once a week (with heparin used for the other two treatments each week) was superior to a regimen in which heparin locks were used after all the treatments; the

Figure 12.51 Arteriovenous (radiocephalic) fistula. (a) In the left forearm. (b) One way of reminding the anaesthetic, nursing and surgical team about the presence of an existing arteriovenous fistula in a haemodialysis patient about to undergo surgery. In particular, the fistula should not be compressed during surgery to avoid thrombosis within it.

rate of access failure was halved, and access-related infection was reduced by two-thirds.

Dialysis prescription

Dialysis must be tailored to an individual patient to obtain optimal results.

Initiation of dialysis

In clinical practice there is a wide variation in the timing of the starting dialysis therapy in patients with stage 5 CKD. There is a general tendency to start dialysis earlier with eGFR close to 15 mL/min rather than below 10 mL/min, despite a recent study showing that early initiation of dialysis was not associated with an improvement in survival or clinical outcomes. This underscores the fact that decisions about the timing of starting dialysis therapy should be taken individually rather than by a numerical parameter.

Dry weight

This is the weight at which a patient is neither fluid overloaded nor depleted. Patients are weighed at the start of each dialysis session and the transmembrane pressure adjusted to achieve fluid removal equal to the amount by which they exceed their dry weight.

The dialysate buffer

The dialysate buffer is usually acetate or bicarbonate. The sodium and calcium concentrations of the dialysate buffer are carefully monitored. A high dialysate sodium causes thirst and hypertension. A high dialysate calcium causes hypercalcaemia, while a low-calcium dialysate combined with poor compliance of medication with oral calcium carbonate and vitamin D may result in hyperparathyroidism.

Frequency and duration

Frequency and duration of dialysis are adjusted to achieve adequate removal of uraemic metabolites and to avoid excessive fluid overload between dialysis sessions. An adult of average size usually receives 4–5 hours' treatment three times a week. Twice-weekly dialysis is adequate only if the patient has considerable residual renal function. However, in a recent study patients treated with haemodialysis six times a week benefited more with respect to the composite outcomes of death or change in left ventricular mass and quality of life but required more frequent interventions related to vascular access.

Short-duration dialysis using very biocompatible high-flux membranes is commonly employed. Advantages include shorter duration of treatment and hence increased patient convenience. Disadvantages include higher cost of the membranes employed and, in all probability, higher prevalence of hypertension in such patients, requiring hypotensive medication. It should not be forgotten that normal kidneys work for 24 hours a day, 7 days a week, and that dialysis is a poor substitute for the natural state.

Adequate/optimal dialysis should be adjusted to individual patients' needs. All patients are anticoagulated (usually with heparin) during treatment as contact with foreign surfaces activates the clotting cascade. In the UK, a small number of patients manage self-supervised home haemodialysis.

Complications

Hypotension during dialysis is the major complication. Contributing factors include: an excessive removal of extracellular fluid, inadequate 'refilling' of the blood compartment from the interstitial compartment during fluid removal, abnormalities of venous tone, autonomic neuropathy, acetate

intolerance (acetate acts as a vasodilator) and left ventricular hypertrophy.

Very rarely, patients may develop anaphylactic reactions to ethylene oxide, which is used to sterilize most dialysers. Patients receiving ACE inhibitors are at risk of anaphylaxis if polyacrylonitrile dialysers are used.

Other potential, rare, complications include the hard-water syndrome (caused by failure to soften water resulting in a high calcium concentration prior to mixing with dialysate concentrate), haemolytic reactions and air embolism.

Adequacy of dialysis

Dialysis treatment is empirical since the size, number and nature of 'uraemic toxins' is unclear. The only true measure of adequacy is patient mortality and morbidity. Adequate nutrition of the patient, as well as adequate dialysis is necessary to reduce morbidity and mortality.

Symptoms of underdialysis are nonspecific and include insomnia, itching and fatigue, despite adequate correction of anaemia, restless legs and a peripheral sensory neuropathy.

Adequacy of dialysis may be assessed by computerized calculation of urea kinetics, requiring measurement of the residual renal urea clearance, the rate of rise of urea concentration between dialysis sessions, and the reduction in urea concentration during dialysis. The dialysis dose is normally defined in terms of urea reduction ratio (URR) and/or equilibrated urea clearance, eKt/V (where K is the dialyser clearance, t is the duration of dialysis in minutes, and V is the urea distribution volume estimated as total body water). Kt/V of 1.0–1.2 and/or URR of 65% per dialysis session is the minimum threshold required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher eKt/V is associated with a better outcome, although no additional benefits of high (1.53) compared with standard (1.16) eKt/V were seen over 5 years' follow-up. It is likely that duration of haemodialysis session is a factor in itself in addition to the efficiency with which small molecules such as urea are cleared. The best haemodialysis outcome data are seen in renal units where long hours (8 h per session) of dialysis are routinely practised.

Haemodialysis is the most efficient way of achieving rapid biochemical improvement, for instance in the treatment of acute kidney injury or severe hyperkalaemia. This advantage is offset by disadvantages such as haemodynamic instability, especially in acutely ill patients with multiorgan disease, and over-rapid correction of uraemia can lead to 'dialysis disequilibrium'. This is characterized by nausea and vomiting, restlessness, headache, hypertension, myoclonic jerking, and in severe instances seizures and coma owing to rapid changes in plasma osmolality leading to cerebral oedema.

These problems have led to the increasing adoption of gentler continuous methods for the treatment of acute kidney injury (see below).

Haemofiltration

This involves removal of plasma water and its dissolved constituents (e.g. K^+ , Na^+ , urea, phosphate) by convective flow across a high-flux semipermeable membrane, and replacing it with a solution of the desired biochemical composition (Fig. 12.52). Lactate is used as buffer in the replacement solution because rapid infusion of acetate causes vasodilatation, and bicarbonate may cause precipitation of calcium carbonate.

Haemofiltration can be used for both acute and CKD and is used in mainland Europe for CKD patients with haemodynamic instability. High volumes need to be exchanged in

FURTHER READING

Cooper BA, Branley P, Bulfone L et al., IDEAL Study. A randomized, controlled trial of early versus late initiation of dialysis. *N Engl J Med* 2010; 363(7): 609–619.

order to achieve adequate small molecule removal, typically a 22 L exchange three times a week for maintenance treatment and 1 L per hour in acute kidney injury. Financial costs of disposable items (such as filters and replacement fluid) are high and only a selected group of patients with ESKD are managed in this way. Modern dialysis machines have built-in facilities to generate online ultrapure water, which has minimized the cost of the procedure and given an option to the clinician to use this technique either as haemofiltration or in combination with dialysis as *haemodiafiltration* to increase middle molecule clearance (e.g. β_2 -microglobulin) and prevent long-term dialysis complications such as dialysis-related amyloidosis, particularly in young, highly sensitized, non-transplantable patients.

Peritoneal dialysis

Peritoneal dialysis utilizes the peritoneal membrane as a semipermeable membrane, avoiding the need for extra-corporeal circulation of blood. This is a very simple, low-technology treatment compared to haemodialysis. The principles are simple (Fig. 12.53).

- A tube is placed into the peritoneal cavity through the anterior abdominal wall (Fig. 12.54).
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolality of the

Figure 12.52 Principles of haemofiltration.

dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (Table 12.25).

- The fluid is changed regularly to repeat the process.

Chronic peritoneal dialysis requires insertion of a soft catheter, with its tip in the pelvis, exiting the peritoneal cavity in the midline and lying in a skin tunnel with an exit site in the lateral abdominal wall (Fig. 12.54).

This form of dialysis can be adapted in several ways.

- **Continuous ambulatory peritoneal dialysis (CAPD).** Dialysate is present within the peritoneal cavity continuously, except when dialysate is being exchanged. Dialysate exchanges are performed three to five times a day, using a sterile no-touch technique to connect 1.5–3 L bags of dialysate to the peritoneal catheter; each exchange takes 20–40 min. This is the technique most often used for maintenance peritoneal dialysis in patients with ESKD.
- **Nightly intermittent peritoneal dialysis (NIPD),** also called automated peritoneal dialysis (APD). An automated device is used to perform exchanges each night while the patient is asleep. Sometimes dialysate is left in the peritoneal cavity during the day in addition, to increase the time during which

Figure 12.54 The siting of a Tenckhoff peritoneal dialysis catheter.

Figure 12.53 Principles of peritoneal dialysis. Water is attracted into the peritoneal cavity depending on the osmolality of the dialysate.

Table 12.25 Range of concentrations (mmol/L) in routinely available CAPD dialysate

Sodium	130–134
Potassium	0
Calcium	1.0–1.75
Magnesium	0.25–0.75
Chloride	95–104
Lactate	35–40
Glucose ^a	77–236
Total osmolality	356–511 mOsm/kg

^aGlucose content is often expressed as g/dL of anhydrous glucose (e.g. 1.36% = 77 mmol/L). An even more hypertonic dialysate (6.36%) is available for acute (intermittent) peritoneal dialysis.

biochemical exchange is occurring. Few trials have demonstrated superiority of APD over CAPD with regard to complications such as peritonitis, fluid status and in anuric patients.

- **Tidal dialysis.** A residual volume is left within the peritoneal cavity with continuous cycling of smaller volumes in and out.

Osmotic removal of excess plasma water and solutes is achieved using hypertonic dialysate (either due to high glucose concentration or icodextrin), which exerts an osmotic 'drag'. Depending on the patient's fluid intake and residual urine output, it may be necessary to use one or more hypertonic dialysate bags daily to achieve fluid balance in CAPD. Fluid overload is a relatively common problem in CAPD, and is due to failure of transport across the peritoneal membrane.

Complications

Peritonitis

Bacterial peritonitis is the most common serious complication of CAPD and other forms of peritoneal dialysis. Clinical presentations include abdominal pain of varying severity (guarding and rebound tenderness are unusual), and a cloudy peritoneal effluent, without which the diagnosis cannot be made. Microscopy reveals a neutrophil count above 100 cells/mL. Nausea, vomiting, fever and paralytic ileus may be seen if peritonitis is severe. The incidence of CAPD-associated peritonitis has been much reduced (to about one episode every 2 patient-years) by use of a Y-disconnect system in preference to previous methods.

CAPD peritonitis must be investigated with culture of peritoneal effluent. Empirical antibiotic treatment is started, with a spectrum which covers both Gram-negative and Gram-positive organisms. Antibiotics may be given by the oral, intravenous or intraperitoneal route; most centres rely on intraperitoneal antibiotics. Common causative organisms are listed in Table 12.26.

Staph. aureus peritonitis should lead to a search for nasal carriage of this organism, and *Staph. epidermidis* peritonitis may indicate contamination from the patient's (or helper's) skin. Relapsing *Staph. epidermidis* peritonitis with an organism with the same antibiotic sensitivity pattern on each occasion may indicate that the Tenckhoff catheter has become colonized: often this is difficult to eradicate without replacement of the catheter under antibiotic cover.

Gram-negative peritonitis may complicate septicaemia from urinary or bowel infection. A mixed growth of Gram-negative and anaerobic organisms strongly suggests bowel perforation, and is an indication for laparotomy.

Table 12.26 Some causes of CAPD peritonitis^a

	Approximate cases (%)
<i>Staphylococcus epidermidis</i>	40–50
<i>Escherichia coli</i> , <i>Pseudomonas</i> and other Gram-negative organisms	25
<i>Staphylococcus aureus</i>	15
<i>Mycobacterium tuberculosis</i>	2
<i>Candida</i> and other fungal species	2

^aIn approximately 20%, no bacteria are found.

Fungal peritonitis often follows antibacterial treatment but may occur *de novo*. Clinical presentation is very variable. It is rare to be able to cure fungal peritonitis without catheter removal as well as antifungal treatment. Intraperitoneal amphotericin has been associated with the formation of peritoneal adhesions.

Infection around the catheter site

Infection where the catheter exits through the skin is relatively common. It should be treated aggressively (with systemic and/or local antibiotics) to prevent spread of the infection into the subcutaneous tunnel and the peritoneum. The most common causative organisms are staphylococci, including MRSA. Exit site infections can be reduced by routine use of mupirocin or gentamicin ointments locally and intranasally in those with colonized nares. Exit site infection due to *Pseudomonas* is treated by antibiotics and resiting the exit following catheter exchange.

Other complications

CAPD is often associated with constipation, which in turn may impair flow of dialysate in and out of the pelvis. Occasionally, dialysate may leak through a diaphragmatic defect into the thoracic cavity, causing a massive pleural 'effusion'. The glucose content of the effusion is usually diagnostic, or the diagnosis may be made by instillation of methylthioninium chloride (methylene blue) with dialysate and the demonstration of a blue colour on pleural tap. Dialysate may also leak into the scrotum down a patent processus vaginalis.

Failure of peritoneal membrane function is a predictable complication of long-term CAPD, resulting in worsening biochemical exchange and decreased ultrafiltration with hypertonic dialysate. It is thought that this problem may be accelerated by excessive reliance on hypertonic dialysate to remove fluid.

Sclerosing peritonitis is a potentially fatal complication of CAPD. The cause is often unclear, but recurrent peritonitis and exposure of the peritoneum to unphysiological high glucose concentrations is responsible in most cases. Progressive thickening of the peritoneal membrane occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction. CAPD should be abandoned. Improvement may follow renal transplantation or treatment with prednisolone or azathioprine.

Contraindications

There are few absolute contraindications apart from unwillingness or inability on the patient's part to learn the technique.

- Previous peritonitis causing peritoneal adhesions may make peritoneal dialysis impossible, but the extent of adhesions is difficult to predict and it may be worth an attempted surgical placement of a dialysis catheter.
- The presence of a stoma (colostomy, ileostomy, ileal urinary conduit) makes successful placement of a dialysis catheter extremely unlikely.
- Active intra-abdominal sepsis, for instance due to diverticular abscesses, is an absolute contraindication to peritoneal dialysis although diverticular disease per se is not.
- Abdominal hernias may often expand during CAPD as a result of increased intra-abdominal pressure, and should ideally be repaired before or at the time of CAPD catheter insertion.
- Visual impairment may make it difficult for a patient to perform dialysate exchanges, but completely blind patients can be trained in the technique if adequately motivated.
- Severe arthritis makes it difficult to perform the exchanges, but a large number of mechanical aids are available. Sterilization of connections by heat or ultraviolet light reduces the risk of peritonitis.
- Some studies suggest that ESKD patients with coronary artery disease or congestive heart failure have significantly higher morbidity and mortality on CAPD compared with HD. Moreover, elderly patients do worse on CAPD than younger patients. It is advisable to consider HD as the first-choice dialysis modality in these patients where it is possible.

Adequacy of peritoneal dialysis

No consensus exists on the optimum degree of removal of urea and other waste products to be obtained in unit time but there is general agreement that minimum dose delivered should not be <1.7 . Based on observational studies, weekly Kt/V of 2.0 coupled with a creatinine clearance target of 60 L per week had been recommended. However, in a randomized prospective study (ADEMEX), standard daily exchanges of 8 L in total (creatinine clearance 40 L per week) compared with a creatinine clearance of 60 L per week yielded similar patient and technique survival. Peritoneal dialysis inadequacy becomes common when residual renal function declines to zero. With increasing time on treatment, adequacy may become impaired owing to alterations in the efficiency of the peritoneal membrane in transporting waste products, fluid and electrolytes.

Complications of all long-term dialysis

Cardiovascular disease (see p. 620) and sepsis are the leading causes of death in long-term dialysis patients.

Causes of fatal sepsis include peritonitis complicating peritoneal dialysis and *Staph. aureus* infection (including endocarditis) complicating the use of indwelling access devices for haemodialysis.

Dialysis amyloidosis

This is the accumulation of amyloid protein (p. 1043) as a result of failure of clearance of β_2 -microglobulin, a molecule of 11.8 kDa. This protein is the light chain of the class I HLA antigens and is normally freely filtered at the glomerulus but is not removed by cellulose-based haemodialysis membranes. The protein polymerizes, possibly after modification by non-enzymic glycosylation, to form amyloid deposits, which may cause median nerve compression in the carpal tunnel or a dialysis arthropathy – a clinical syndrome of pain

and disabling stiffness in the shoulders, hips, hands, wrists and knees. β_2 -microglobulin-related amyloid may be demonstrated in the synovium. Amyloid deposits (see p. 1043) can also cause pathological bone cysts and fractures, pseudotumours and gastrointestinal bleeding caused by amyloid deposition around submucosal blood vessels. The extent of amyloid deposition is best assessed by nuclear imaging, either using [^{99m}Tc] DMSA, or more specifically, by the use of radiolabelled serum amyloid P component.

Rapid improvement after renal transplantation is probably due to steroid therapy as low-dose prednisolone alone can also cause an improvement. A change to a biocompatible synthetic membrane has also been reported to be of benefit: again, the mechanism for this improvement is not clear. β_2 -microglobulin clearance is several times higher in patients treated with haemofiltration or haemodiafiltration and these techniques are increasingly used in patients at high risk of developing this complication.

Dialysis in the elderly

Dialysis can prolong life, but the benefit to the individual and particularly elderly patients, varies widely. Outcomes in frail elderly people who are undergoing dialysis are poor. Small studies suggest that mortality or quality-of-life outcomes do not differ significantly among selected patients who elect to undergo dialysis compared to those who decide against dialysis. In one study, over 50% died within the first year of initiating dialysis and around 30% had a decrease in functional status.

Prior to the initiation of dialysis, elderly patients must be informed about its modest benefit in their age group and the possibility of conservative therapy that does not involve dialysis. Conservative therapy should be discussed, not as a last resort but as a clear option that might be more effective in promoting patient goals. There is a need for well structured palliative care infrastructure staffed by trained individuals to deal with end of life decision issues in dialysis patients.

Transplantation

Successful renal transplantation offers the potential for almost complete rehabilitation in ESKD. This mode of renal replacement therapy has significant survival advantage compared to dialysis patients on transplant waiting lists. It allows freedom from dietary and fluid restriction; anaemia and infertility are corrected; and the need for parathyroidectomy is reduced. It is the treatment of choice for most patients with ESKD. The supply of donor organs (in the UK, 30/million per year) is greatly exceeded by demand (48/million per year), and donor organs are therefore scarce and a valuable resource that must be used optimally.

The technique involves the anastomosis of an explanted human kidney, usually either from a cadaveric donor or from a living close relative, on to the iliac vessels of the recipient (Fig. 12.55). The donor ureter is placed into the recipient's bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed, for as long as the transplant remains in place, to prevent rejection. Refinements in patient selection and assessment of donor-recipient compatibility, improvements in surgical techniques and the development of more efficient immunosuppressive regimens have increased patient and graft survival. Some 80% of grafts now survive for 5–10 years in the best centres, and 50% for 10–30 years. However, the half-life of renal allografts is still 13–16 years. The three most common causes of late graft loss are death with functioning graft, recurrence of renal disease and chronic allograft nephropathy.

Figure 12.55 Anatomy of a renal transplant operation.

Factors affecting success

ABO (blood group) compatibility between donor and recipient is required. However, in some centres, particularly in Japan where a cadaveric organ donation programme is not well established, ABO-incompatible renal transplants are increasingly performed. These transplants follow with immunoadsorption to remove preformed antibodies, splenectomy, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies. In experienced hands, results are acceptable.

Matching donor and recipient for HLA type

Matching for HLA-DR antigens appears to have the most impact on graft survival. Studies have shown that matching at the HLA-B locus has only a minor effect on graft outcomes. Complete compatibility at A, B and DR offers the best chance of success, followed by a single HLA mismatch (i.e. antigen possessed by the donor and not possessed by the recipient). The effect of further degrees of mismatching upon graft survival in first transplants is of modest degree. Nationwide matching schemes for kidneys retrieved from cadaver donors are in existence. However, with availability of more efficient immunosuppressive agents, the value of HLA matching in the overall transplant outcome is, if any, only modest. Transplantation with completely mismatched kidneys, particularly when the donor is the patient's partner, is routinely practised and results are as good as, if not better than, properly matched cadaveric kidneys.

A donor factor, an allotype of the C3 complement molecule, may be associated with better long-term outcomes for cadaveric kidney grafts. This report raised the possibility that the presence of the C3F (fast) allele in a kidney allograft is associated with a better outcome. However, this finding could not be reproduced in a subsequent study, which underscores the necessity of validation of unusual findings by several groups before adopting them in the clinical practice.

Adequate immunosuppressive treatment

See below.

The donor kidney

Cadaveric donation

Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage ('brainstem death') while their hearts are still beating (see p. 897). Due to shortage of solid organs and increasing numbers

of patients waiting for them, several countries now allow the retrieval of organs after cardiac death, with comparable results to heart beating donations. Moreover, elderly donors (age >60 years) or those between the ages of 55 and 59 years but co-morbidity such as hypertension, diabetes, preretrial AKI and intracranial haemorrhage as a cause of death known as expanded criteria donors (ECD) are increasingly used.

Living related donation

A close relative may volunteer as a potential donor. A sibling donor may be HLA identical or share one or no haplotypes with the potential recipient. In the UK, donor age must be 18 years or more.

Potential living related donors are subjected to an intensive preoperative evaluation, including clinical examination and measurement of renal function, tests for carriage of hepatitis B, C, HIV and cytomegalovirus, and detailed imaging of renal anatomy, to be sure that transplantation will be technically feasible.

Unrelated living donors may be accepted provided no inducement (financial or otherwise) is involved. Paid live non-related donor transplantation is illegal in the UK.

Immunosuppression for transplantation

Long-term drug treatment for the prevention of rejection is employed in all cases apart from living related donation from an identical twin. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months, rejection episodes occur in less than 30% of cadaver kidney recipients. Most are reversible. A combination of immunosuppressive drugs is usually used (Table 12.27).

Complications

Acute tubular necrosis (ATN)

ATN is the commonest cause of cadaveric graft dysfunction (up to 40–50%), particularly in kidneys from DCD or ECD donors and prolonged cold ischaemia time (>24 hours). Delayed graft function due to ATN is associated with worse long-term outcome and also predisposes the graft to rejection. It is usual practice to use induction with antibodies and use 50% of the starting dose of calcineurin inhibitors in recipient of grafts at high risk for ATN.

Technical failures

There may be occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis, and urinary leaks owing to damage to the lower ureter, or defects in the anastomosis between ureter and recipient bladder. If urine output drops, Doppler ultrasonography, DTPA scanning and/or renal angiography is used. Surgical reimplantation may be required.

Acute rejection (AR)

AR is seen in between 10% and 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy confirms the diagnosis and also assesses the severity and type of rejection (cellular or vascular or antibody mediated, also called humoral rejection). Therapy in cellular rejection is high-dose pulse steroid; in acute vascular rejection (diagnosed by the presence of additional endothelial inflammation), ATG, anti-lymphocyte globulin (ALG) or OKT3 is used.

Histological appearances similar to vascular rejection are seen in a small number of patients where the culprit is an agonistic antibody directed against angiotensin receptor 1 (ATR 1), which usually presents with sudden decline in renal

Table 12.27 Immunosuppressive drugs used in renal transplantation

Class	Mechanism of action	Examples	Clinical role	Side-effects
Calcineurin inhibitors	Disrupt T-cell signalling	Ciclosporin Tacrolimus	Mainstay of most regimens	Nephrotoxicity (monitor levels), hypertension, diabetes, hirsutism, virilization
Inhibitors of purine synthesis	Inhibit purine synthesis and hence active proliferation of cells (especially lymphocytes)	Azathioprine Mycophenolate mofetil (MMF)	Used in most regimens	Neutropenia, pancytopenia, deranged LFTs (azathioprine), diarrhoea (MMF) Interaction with allopurinol (azathioprine)
Steroids	Inhibition of cytokine-regulated T-cell signalling	Prednisolone (oral) Methylprednisolone (i.v.)	Used in most regimens. Dose tapers over first few weeks i.v. methylprednisolone used on induction and to treat acute rejection	Multiple, including osteoporosis, hypertension, diabetes, weight gain, poor wound healing, lipid abnormalities
Rapamycin (Sirolimus)	Inhibits cytokine-dependent cell proliferation		Role still being explored. Alternative to calcineurin inhibitors	Delayed graft function, myelosuppression, impaired wound healing, thrombocytopenia Levels should be monitored
Anti-CD25 antibodies	Monoclonal antibody, blocking the IL-2 receptor	Daclizumab Basiliximab	Given on induction. Usually used in patients with medium-high risk of rejection	Well tolerated
Antibodies causing T-cell depletion	Targets and destroys T cells	Anti-thymocyte globulin (ATG) = polyclonal OKT3 = monoclonal anti-CD3 antibody	For steroid-resistant rejection (7–10-day course). May be used as induction agent for patients at high risk of rejection	Severe T-cell depletion (risk of sepsis) Late development of malignancy, esp. lymphoma
Anti-CD52 antibody	Depletes both T and B cells	Alemtuzumab	Used as induction agent	Over-immunosuppression, risk of sepsis and malignancy in longer term Long-term outcome data awaited
Anti B7 antibody	Prevents engagement of B7 and CD28 Blocking co-stimulatory signal	Belatacept	Has been tried with success in maintenance regimens instead of calcineurin inhibitors	Relatively high but mild rejection. High incidence of post-transplant lymphoma in EBV negative patients
Anti-C5a antibody	Inhibits complement activation by blocking activated C5	Eculizumab	Success in acute antibody mediated rejections. Atypical HUS post-transplant	Infections particularly meningococcal meningitis. Patients should be vaccinated against meningitis prior to its use

Figure 12.56 Histology of kidney in rejection. (a) Acute vascular rejection: the mononuclear inflammatory cell infiltrate is limited to the expanded intima and does not involve the entire vascular wall as in systemic vasculitis. (b) Antibody mediated rejection: an acute tubular necrosis with capillary glomerulitis and peritubular and glomerular capillary C4d positivity.

function but unlike vascular rejection also manifests with malignant phase hypertension and seizures. It responds to angiotensin receptor blockers in addition to conventional antirejection strategies (Fig. 12.56a). Humoral rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on renal

biopsy by C4 staining) (Fig. 12.56b) is usually treated empirically by a combination of i.v. polyclonal immunoglobulin infusion to neutralize and promote the clearance of anti-HLA antibodies, plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes) with variable success.

More than one rejection within the first 3 months, vascular and/or humoral rejection, delayed rejection (requirement of dialysis within the first week after transplantation), and failure of serum creatinine to return to baseline ($<130 \mu\text{mol/L}$) are associated with worse long-term outcome. The outcome of renal transplantation during an episode of acute rejection is difficult to predict, even with an allograft biopsy. Urinary levels of messenger RNA (mRNA) for FOXP3, a specification and functional factor for regulatory T lymphocytes, improve the prediction of outcome of acute rejection of renal transplants by a non-invasive means. It predicts with a reasonable degree of sensitivity and specificity successful outcome or otherwise in a renal transplant with acute rejections.

Infections

In the first month post-transplantation, infections tend to be from bacterial sources seen typically in the surgical population. Cytomegalovirus (CMV) infections develop weeks or months after transplantation in 70% of CMV-seronegative recipients receiving grafts from a seropositive donor and in patients receiving biological agents (antibodies) as induction or therapy for rejection, unless prophylaxis with valganciclovir is given. Prophylaxis is also routinely given against *Pneumocystis jiroveci* (co-trimoxazole) and oral candidiasis (nystatin or amphotericin lozenges). Polyomavirus infections (BK nephropathy) result in graft dysfunction and eventual loss due to mainly tubulointerstitial nephritis diagnosed by renal biopsy and presence of cellular inclusion bodies positive for SV40 (Fig. 12.57). There is no known specific treatment with the exception of tapering immunosuppression and with cautious use of leflunomide and cidofovir.

Post-transplantation lymphoproliferative disorders

Epstein-Barr virus-associated malignancies are common in patients who received biological agents and in children. Tapering of ciclosporin or tacrolimus, cessation of antiproliferative agents (azathioprine or MMF) and monitoring for the reappearance of cytotoxic lymphocytes has improved the outcome.

Chronic allograft nephropathy (CAN)

CAN remains the most common cause of late graft failure. The process is mediated by immunological possibly due to chronic antibody mediated rejection due to *de novo* synthesis of donor specific antibodies and non-immunological factors and results in a progressive irreversible decline in graft function with mild to modest proteinuria ($<3 \text{ g/day}$). Unfortunately there is no established therapy of proven efficiency.

Figure 12.57 BK nephropathy showing the characteristic intranuclear viral inclusion with positive immunohistological stain for SV40.

Malignancy

Immunosuppressive therapy increases the risk of skin tumours, including basal and squamous cell carcinoma. In white recipients, exposure to ultraviolet light should be minimized and sun-block creams employed. Other common cancers are renal, cervical and vaginal. In female recipients, regular yearly cervical smears should be carried out.

Cardiovascular disease

Cardiovascular disease is the cause of death post transplantation in 50% of cases. This is due to increased incidence of hypertension, obesity, diabetes and insulin resistance lipid disorders. Use of a statin (fluvastatin) was associated with reduction in cardiac endpoints (myocardial infarction or revascularization) post transplantation but overall mortality remained unchanged in a randomized prospective study.

Post-transplant osteoporosis

This is common following transplantation owing to treatment with steroids. Maximum bone loss occurs within the first 3 months and regular DXA scans are necessary. Bisphosphonates (alendronate, pamidronate) and alfacalcidol with or without calcium carbonate have proven to be effective in control studies.

Recurrent disease

Recurrence of renal disease is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur with variable effects on long-term graft survival.

Renal transplantation in HIV patients

Modern highly active antiretroviral therapy (HAART) offers patients with HIV infection a near-normal life expectancy. However, an increasing number develop end-stage CKD. Until recently, HIV was considered to be a contraindication to renal transplantation. Nevertheless, a recent study of outcomes for 150 HIV-infected patients undergoing renal transplantation has shown that kidney transplantation is safe and effective in patients, at least in the short term. The patients in the study had CD4^+ T-cell counts $\geq 200/\text{mL}^3$ and undetectable plasma levels of HIV type 1 RNA while on stable HAART during the 16 weeks before renal transplantation. Median follow-up was 1.7 years. Survival rates at 1 year (95%) and 3 years (88%) were worse in HIV-infected patients than in the general population of kidney transplant recipients, but better than those in patients aged ≥ 65 years. Many rejection episodes were glucocorticoid-resistant, suggesting an aggressive response to donor antigens.

CYSTIC RENAL DISEASE

Solitary or multiple renal cysts are common, especially with advancing age: 50% of those aged 50 years or more have one or more such cysts. They have no special significance except in the differential diagnosis of renal tumours (see p. 634). Such cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. Occasionally, they may cause pain and/or haematuria owing to their large size, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts which enlarge with time) occurs regularly in the kidneys of patients with ESKD treated by dialysis and/or transplantation. Malignant tumour formation seems to be more common in such kidneys than in the general population.

Hildebrandt F et al. Ciliopathies. *N Engl J Med* 2011; 364: 1533–1543.

Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder usually presenting in adult life. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000 in white populations. It accounts for 3–10% of all patients commencing regular dialysis in the West (see ciliopathies, p. 22).

In about 85% of cases, the gene responsible (*PKD1*) has been located on chromosome 16. A second gene, *PKD2*, which has been mapped to chromosome 4, accounts for the vast majority of other cases. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the *PKHD1* gene on chromosome 6p21.1-p12), which is often lethal in early life.

The protein corresponding to the *PKD1* gene, polycystin 1, is an integral membrane glycoprotein involved in cell-to-cell and/or cell-to-matrix interaction and functions as a mechanosensor. The protein corresponding to the *PKD2* gene appears to function as a calcium ion channel, regulating calcium influx and/or release from intracellular stores. Polycystin-1 acts as the regulator of PKD2 channel activity by its co-localization on cilia of collecting tubular cells. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which in principal cells (p. 662) of the collecting duct causes an increase in cAMP via stimulation of calcium-inhibitable adenylyl cyclase and inhibition of cAMP phosphodiesterases. Defective ciliary signalling results in disoriented division of the cells by upregulation of mammalian target of rapamune (mTOR) and its downstream cell cyclin kinases along the nephron, resulting in cyst formation. In ADPKD, <1% of all nephrons acquire a second somatic mutation that in combination with a germline mutation results in cystogenesis. Progressive loss of renal function is usually attributed to mechanical compression, apoptosis of the healthy tissue and reactive fibrosis. Patients with ADPKD experience declining renal function at a variable rate which is due to discrepancy in the growth and size of the cysts; patients with rapid growth in cyst size as determined by MRI lose renal function more rapidly. Strategies to slow the growth rate of cysts have been very effective in preserving renal function in animal models. These therapies include the vasopressin V₂ receptor inhibitor (vaptan, to reduce cAMP in the principal cells), roscovitine (a cyclin-dependent kinase inhibitor) and antiproliferative therapy with sirolimus (mTOR inhibitor).

Clinical features

Clinical presentation may be at any age from the second decade. Presenting symptoms include:

- Acute loin pain and/or haematuria owing to haemorrhage into a cyst, cyst infection or urinary tract stone formation
- Loin or abdominal discomfort owing to the increasing size of the kidneys
- Subarachnoid haemorrhage associated with berry aneurysm rupture
- Complications of hypertension
- Complications of associated liver cysts
- Symptoms of uraemia and/or anaemia associated with CKD.

Erythraemia is a rare complication and presentation of ADPKD.

The natural history of the disease is one of progressive CKD, sometimes punctuated by acute episodes of loin pain and haematuria, and commonly associated with the development of hypertension. The rate of progression to CKD (see above) is variable. The determinants of progression are both genetic and non-genetic. In the PKD2 form, renal cysts develop more slowly and ESKD occurs 10–15 years later than in the PKD1 form. Gender affects renal prognosis. Males with ADPKD reach ESKD 5–6 years earlier than females. There is a large variability in the age at end-stage renal failure within families, even between affected monozygotic twins.

Complications and associations

Pain

A minority of patients suffer chronic renal pain resistant to common analgesics, presumably owing to the pressure effect of large cysts. Surgical decompression of such cysts appears to be of benefit in about two-thirds of patients. Laparoscopic cyst decortication is a minimally invasive alternative technique.

Cyst infection

The response to standard antibacterial therapy is often poor owing to poor penetration of conventional antibiotics across the cyst wall. Lipophilic antibiotics active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones, penetrate into the cysts better and their use has greatly improved the treatment of this complication.

Renal calculi

These are diagnosed in about 10–20% of patients with ADPKD. Frequently, they are composed of uric acid and hence, radiolucent (see Fig. 12.39). Obstructing or painful stones are treated no differently than are stones in patients with normal urinary tracts. Percutaneous stone removal and extracorporeal lithotripsy is safe.

Hypertension

Hypertension is an early and very common feature of ADPKD. Elevation of blood pressure, still within the normal range, is detectable in young affected individuals and is associated with an increase in left ventricular mass. Left ventricular hypertrophy occurs to a greater degree for a given rise in blood pressure in ADPKD compared with other renal disorders and with essential hypertension. Intrarenal activation of the renin-angiotensin system is involved in pathogenesis, and ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as cardiovascular complications are a major cause of death in ADPKD.

Progressive CKD

This is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is more rapid than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is of the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are better than those in patients with other primary renal diseases.

Hepatic cysts

Approximately 30% of patients have hepatic cysts and in a minority of the patients massive enlargement of the polycystic liver is seen. Pain, infection of cysts and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow occur. Rarely, percutaneous drainage of painful

Figure 12.58 Ultrasound scan of a polycystic kidney, showing an enlarged kidney with many cysts of varying size.

cysts, laparoscopic fenestration or even partial hepatectomy is necessary. Infected cysts may require drainage.

Intracranial aneurysm formation

About 10% of ADPKD patients have an asymptomatic intracranial aneurysm (see p. 1105) and the prevalence is twice as high in the subgroup of patients with a family history of such aneurysms or of subarachnoid haemorrhage. Such haemorrhage is preceded in from 20% to 40% of cases by premonitory headaches from a few hours up to 2 weeks before the onset of subarachnoid bleeding. Headache of sudden onset or unusual character or severity in a patient with ADPKD should prompt investigation. Contrast-enhanced spiral CT or MR angiography are the best investigations. Screening for intracranial aneurysm in ADPKD is currently recommended for patients aged 18–40 years who have a positive family history.

Mitral valve prolapse

This is found in 20% of individuals with ADPKD.

Diagnosis

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 12.58). However, such renal imaging techniques may be equivocal, especially in subjects under the age of 15 years.

Differential diagnosis

A number of conditions can mimic clinical and radiological appearance of PKD (Box 12.7).

Screening

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Screening by ultrasonography should not be carried out before the age of 15 years (Box 12.8), as excluding the condition may be difficult and hypertension is unusual before this age. Even at the age of 30 years, renal ultrasonography may give a false-negative result. Gene linkage analysis can be utilized in many families.

Therapy

No therapy is yet available but potential agents include *vasopressin receptor antagonists*, which have been studied in animal models of polycystic kidney disease, closely related to human ADPKD, where they have halted cyst progression or caused disease regression. ADPKD kidneys may be particularly vulnerable to *adenylyl cyclase agonists* or *cAMP phosphodiesterase inhibitors*. Tolvaptan (which acts by inhibiting cAMP in principal cells) is already being used in clinical

Box 12.7 Conditions that clinically and radiologically mimic polycystic kidney disease

- **Tuberous sclerosis:** includes lymphangiomyomatosis and lymphangioleiomyomatosis and can be associated with the TSC2–PKD1 contiguous gene syndrome
- **von Hippel–Lindau syndrome**
- **Multicystic dysplastic kidney:** a non-heritable unilateral syndrome or a systemic syndrome (e.g. prune belly syndrome)
- **Juvenile nephronophthisis** and medullary cystic kidney disease: can be autosomal recessive (presenting in the 2nd decade of life) or autosomal dominant (presenting in the 3rd to 4th decades)
- **Glomerulocystic kidney disease:** involves the expansion of Bowman's space and is autosomal dominant
- **Acquired cystic disease:** involves end-stage renal disease and hypokalemia
- **Renal-cell carcinoma** with cystic changes

Box 12.8 Ultrasonographic diagnostic criteria for testing individuals at risk of ADPKD

In at-risk individuals a diagnosis of ADPKD is established if patients meet the following criteria:

- 15–39 years: ≥ 3 cysts (unilateral or bilateral)
- 40–59 years: ≥ 2 cysts in each kidney
- ≥ 60 years: ≥ 4 cysts in each kidney

ADPKD is excluded in patients meeting the following criteria:

- ≥ 40 years: < 2 cysts
- 30–39 years: 0 cysts (this excludes ADPKD in 98% of cases).

At < 30 years, a negative renal ultrasound scan does not exclude a diagnosis of ADPKD; other imaging techniques such as CT and MRI may be useful and molecular genetic testing might be needed.

trials. However, in a small study, octreotide, a long-acting somatostatin analogue (which inhibits cAMP), was beneficial in halting the growth of both liver and renal cysts. Caffeine at clinically relevant concentrations has been found to enhance the effect of desmopressin to stimulate chloride secretion in cultured epithelial cells from ADPKD cysts. Two studies of mTOR inhibitor on PKD were essentially negative for primary end point of cyst growth and preservation of renal function.

Medullary cystic disease ('juvenile nephronophthisis')

Juvenile nephronophthisis that develops early in childhood is commonly inherited in an autosomal recessive manner. Mutations in the genes *NPHP1–4* are present. The proteins mutated, nephrocystin and inversin, are co-localized in the cilia of the renal tubules. A similar condition developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait, but sporadic cases occur in both conditions. Despite its name, the dominant histological finding is interstitial inflammation and tubular atrophy, with later development of medullary cysts. Progressive glomerular failure is a secondary consequence.

The dominant features are polyuria, polydipsia and growth retardation. Diagnosis is based on the family history and renal biopsy, the cysts rarely being visualized by imaging techniques.

Medullary sponge kidney

Medullary sponge kidney is an uncommon but not rare condition that usually presents with renal colic or haematuria. Although it is most often sporadic, a few affected families have been reported. The condition is characterized by dilatation of the collecting ducts in the papillae, sometimes with cystic change. In severe cases the medullary area has a sponge-like appearance. The condition may affect one or both kidneys or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients there is associated hypercalciuria or renal tubular acidosis (see p. 664). Hemihypertrophy of the skeleton has been described in this condition.

The diagnosis is made by excretion urography, which shows small calculi in the papillary zones with an increase in radiodensity around these following injection of contrast medium as the dilated or cystic collecting ducts are filled with contrast (see Fig. 12.37).

The natural history is one of intermittent colic with passage of small stones or haematuria. Renal function is usually well maintained and CKD is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

TUMOURS OF THE KIDNEY AND GENITOURINARY TRACT**Malignant renal tumours**

These comprise 1–2% of all malignant tumours, and the male to female ratio is 2:1.

Renal cell carcinoma

Renal cell carcinomas (RCC) arise from proximal tubular epithelium. They are the most common renal tumour in adults. They rarely present before the age of 40 years, the average age of presentation being 55 years.

In von Hippel–Lindau disease, an autosomal dominant disorder, bilateral renal cell carcinomas are common and haemangioblastomas, pheochromocytomas and renal cysts are also found. Polymorphic probes from chromosome 3p, the region implicated in renal cell carcinoma, have demonstrated genetic linkage between this tumour and von Hippel–Lindau disease. It seems likely, therefore, that mutation of the same tumour suppressor gene is responsible for both renal cell carcinoma and von Hippel–Lindau disease. Deletion of the short arm of chromosome 3 is the most consistent cytogenetic finding in sporadic tumours.

Renal cell carcinomas are highly vascular tumours; microscopically most tumours are composed of large cells containing clear cytoplasm.

Clinical features

Patients are often asymptomatic but can present with haematuria, loin pain and a mass in the flank. Malaise, anorexia and weight loss (30%) occur, and 5% of patients have polycythaemia (see p. 404). Some 30% of patients have hypertension (due to secretion of renin by the tumour) and anaemia, due to depression of erythropoietin in approximately the same number. Pyrexia is present in about one-fifth of patients and approximately one-third present with metastases. Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

Diagnosis

Ultrasonography is used to demonstrate the solid lesion and to examine the patency of the renal vein and inferior vena cava. CT scanning is used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Renal arteriography will reveal the tumour's circulation but is now seldom employed. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

Treatment

Medical management of renal cell carcinoma is discussed in Chapter 9. A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted since regression of metastases has been reported after removal of the main tumour mass.

Nephroblastoma (Wilms' tumour)

This tumour is seen mainly within the first 3 years of life and may be bilateral. It presents as an abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT and MRI. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

Urothelial tumours

The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell tumours account for about 3% of deaths from all forms of malignancy. Such tumours are uncommon below the age of 40 years, and the male to female ratio is 4:1. Bladder tumours are about 50 times as common as those of the ureter or renal pelvis. Pre-disposing factors include:

- Cigarette smoking
- Exposure to industrial carcinogens such as β -naphthylamine and benzidine (workers in the chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid found in some herbal weight-loss preparations
- Exposure to drugs (e.g. phenacetin, cyclophosphamide)
- Chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

Presentation

Painless haematuria is the most common presenting symptom of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI develop in the absence of significant bacteriuria. In patients with bladder cancer, pain also results from local nerve involvement. Presenting symptoms may result from local metastases.

Transitional cell carcinomas in the kidney and ureter also present with haematuria. They may also give rise to flank pain, particularly if urinary tract obstruction is present.

Investigations

Cytological examination of urine for malignant cells and renal imaging (ultrasonography, CT and MRI) should be performed in all patients. Cystoscopy is necessary unless pathology is

found in the upper urinary tract. It may be omitted in men under 20 and women under 30 years if significant bacteriuria accompanies the haematuria and ceases following control of the infection, provided urine cytology and renal imaging are normal. With these exceptions, haematuria should always be investigated. In cases where the tumour is not clearly outlined on ultrasonography or CT, retrograde ureterography may be helpful.

Treatment

Medical management of urothelial and testicular tumours is discussed in Chapter 9, page 481.

DISEASES OF THE PROSTATE GLAND

Benign enlargement of the prostate gland

Benign prostatic enlargement occurs most often in men over the age of 60 years. Such enlargement is much less common in Asian individuals. It is unknown in eunuchs. The aetiology of the condition is unknown. Microscopically, hyperplasia affects the glandular and connective tissue elements of the prostate. Enlargement of the gland stretches and distorts the urethra, obstructing bladder outflow.

Clinical features

Frequency of urination, usually first noted as nocturia, is a common early symptom. Difficulty or delay in initiating urination, with variability and reduced forcefulness of the urinary stream and post-void dribbling, are often present. Acute retention of urine (see below) or retention with overflow incontinence may occur. Occasionally, severe haematuria results from rupture of prostatic veins or as a consequence of bacteriuria or stone disease. Occasional patients present with severe CKD.

Abdominal examination for bladder enlargement together with examination of the rectum is essential. A benign prostate feels smooth. An accurate impression of prostatic size cannot be obtained on rectal examination.

Management and prognosis

Patients with mild-to-moderate symptoms should be managed by 'watchful waiting', because symptoms following therapy are sometimes greater than those with no therapy at all.

Patients with moderate prostatic symptoms can be treated medically. A number of drugs have been employed, including alpha-blockers such as tamsulosin. Finasteride is a competitive inhibitor of 5 α -reductase, which is the enzyme involved in the conversion of testosterone to dihydrotestosterone. This is the androgen primarily responsible for prostatic growth and enlargement. Finasteride decreases prostatic volume with an increase in urine flow. Deterioration in renal function or the development of upper tract dilatation requires surgery.

In acute retention or retention with overflow, the first priorities are to relieve pain and to establish urethral catheter drainage. If urethral catheterization is impossible, suprapubic catheter drainage should be carried out. The choice of further management is then between immediate prostatectomy, a period of catheter drainage followed by prostatectomy, or the acceptance of a permanent indwelling suprapubic or urethral catheter.

Prostatic carcinoma

Prostatic carcinoma accounts for 7% of all cancers in men and is the sixth most common cancer in the world. Malignant change within the prostate becomes increasingly common with advancing age. By the age of 80 years, 80% of men have malignant foci within the gland, but most of these appear to lie dormant. Histologically, the tumour is an adenocarcinoma. Hormonal factors are thought to play a role in the aetiology.

Clinical features

Presentation is usually with symptoms of lower urinary tract obstruction; less common are symptoms of metastatic spread, e.g. back pain, weight loss or anaemia. The diagnosis is also made by the incidental finding of a hard irregular gland on rectal examination, or as an unexpected histological result after prostatectomy for what was believed to be benign prostatic hypertrophy.

In developed countries, patients now present as a result of screening for prostate cancer by measurement of prostate-specific antigen (PSA). However, on the evidence available, national programmes of screening are not justified. Treatment of well people carries a high morbidity of urinary incontinence and sexual dysfunction with no evidence as yet of increased overall survival. In future, screening of 'at-risk' groups may be useful. PSA >4 ng/mL is abnormal but between 4 and 10 ng/mL this can be due to benign hypertrophy and cancer. If PSA is over 10 ng/mL, a prostatic biopsy will show cancer in over 50% of cases.

Investigations

These include transrectal ultrasound of the prostate and prostatic biopsy. A histological diagnosis is essential before treatment. The Gleason scoring system is based on the histological appearances. If metastases are present, serum prostate-specific antigen levels are usually markedly elevated (>16 ng/mL) but can be normal; it is a myth that elevated levels occur as a result of rectal examination.

Ultrasonography and transrectal ultrasonography are also of value in defining the size of the gland and staging any tumour present. Endorectal coil MRI helps to detect extra-prostatic extension. The upper renal tracts can be examined by ultrasonography for evidence of dilatation. Bone metastases appear as osteosclerotic lesions on X-ray and are also detected by isotopic bone scans.

Treatment

Non-surgical treatment of prostatic carcinoma is discussed in Chapter 9, page 481. Microscopic, impalpable tumours can sometimes be managed expectantly. Treatment for disease confined to the gland is radical prostatectomy (provided the patient is fit for the procedure) or radiotherapy. Metastatic disease can be treated with orchidectomy, but many men refuse.

URINARY PROBLEMS IN THE ELDERLY

Progressive sclerosis of glomeruli occurs with ageing and this, together with the development of atheromatous renal vascular disease, accounts for the progressive reduction in GFR seen with advancing years. A GFR of 50–60 mL/min (about half the normal value for a young adult) may be regarded as 'normal' in patients in their eighties. The

reduction in muscle mass often seen with ageing may mask this deterioration in renal function in that the serum creatinine concentration may be less than 120 $\mu\text{mol/L}$ in an elderly patient whose eGFR is 50 mL/min or lower. The use of serum creatinine as a measure of renal function in the elderly must take this into account. This is especially so in the elderly when prescribing drugs whose excretion is in whole or in part by the kidney.

Urinary tract infections

UTIs are common in the elderly, in whom impaired bladder emptying due to prostatic disease in males and neuropathic bladder – especially common in females – is frequently found. Symptoms may be atypical, the major complaints being incontinence, nocturia, smelly urine or vague change in well-being with little in the way of dysuria. Demonstration of significant bacteriuria in the presence of such symptoms requires treatment.

Urinary incontinence

This is defined as involuntary passage of urine sufficient to be a health or social problem. It is common in the elderly with 25% of women and 15% of men over 65 having a problem.

- **Urge incontinence** is usually due to detrusor overactivity with leakage of urine because the bladder is perceived to be full. This is common in the elderly; it occurs as an isolated event or secondary to local factors, e.g. bladder infection or stones, or to central factors, e.g. stroke, dementia or Parkinson's disease.
- **Stress incontinence** occurs when the intra-abdominal pressure is increased, e.g. after a cough or sneeze and there is a weak pelvic floor or urethral sphincter. It is common in women after childbirth.
- **Overflow incontinence** occurs with leakage of urine from a full distended bladder. It occurs commonly in men with prostatic obstruction, following spinal cord injury or in women with cystoceles or after gynaecological surgery.
- **Functional incontinence.** Passage of urine occurs owing to inability to get to a toilet because of disability, e.g. stroke, trauma, the unavailability of toilet facilities or dementia.

Management

- Physical examination for local problems, e.g. prostatic enlargement in men, gynaecological disorders in women, and for central problems, e.g. neurological disorders or dementia
- Urine analysis, e.g. glycosuria and culture for UTI
- Treatment of contributing causes, e.g. constipation, drug therapy, other co-existing disease
- Urge incontinence – bladder training, antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin and darifenacin

- Stress incontinence – pelvic floor exercises. Transurethral injections of autologous myoblasts can aid in regeneration of the rhabdosphincter, and fibroblasts in reconstruction of the urethral submucosa. Effectiveness and tolerability of ultrasonography-guided injections of autologous cells is greatly superior compared with those of endoscopic injections of collagen for stress incontinence. Mid-urethral slings are increasingly used for the treatment of stress incontinence either by retropubic and transobturator approach with comparable efficiency
- Overflow – removal of obstruction
- Functional – improve facilities, regular urine voiding, absorbent padding.

Further evaluation with urodynamics is necessary in patients who do not respond and have a potentially curable problem. An expert and committed incontinence advisory and treatment service combining nursing and medical skills is invaluable for elderly patients with this distressing problem. Home visits to ensure the availability of commodes and toilets are essential. For established incontinence, catheterization may be necessary but should be avoided if at all possible. Incontinence and its treatment are matters of major importance and are by no means confined solely to the elderly.

DISTRIBUTION AND COMPOSITION OF BODY WATER

In normal, healthy people, the total body water constitutes 50–60% of lean bodyweight in men and 45–50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- Intracellular fluid (28 L, about 35% of lean bodyweight)
- Extracellular – the interstitial fluid that bathes the cells (9.4 L, about 12%)
- Plasma (also extracellular) (4.6 L, about 4–5%).

In addition, small amounts of water are contained in bone, dense connective tissue, and epithelial secretions, such as the digestive secretions and cerebrospinal fluid.

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 13.1). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a semi-permeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in the compartments differ, each having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure:

- The intracellular fluid contains mainly potassium (K^+) (most of the cell Mg^{2+} is bound and osmotically inactive)
- In the extracellular compartment, Na^+ salts predominate in the *interstitial fluid*, and proteins in the plasma.

Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to

hold water in the vascular space by an oncotic effect which is, in part, counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction (Fig. 13.1). The composition of intracellular and extracellular fluids is shown in Table 13.1.

A characteristic of an osmotically active solute is that it cannot freely leave its compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is 'impermeable' to Na^+ and K^+ because the Na^+/K^+ -ATPase pump largely restricts Na^+ to the extracellular fluid and K^+ to the intracellular fluid. By contrast, Na^+ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

A conclusion from these observations is that body Na^+ stores are the primary determinant of the extracellular fluid volume. Thus, the extracellular volume – and therefore tissue perfusion – are maintained by appropriate alterations in Na^+ excretion. For example, if Na^+ intake is increased, the extra Na^+ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na^+ in the urine.

Distribution of different types of replacement fluids

Figure 13.2 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions. Thus, 1 L of water given intravenously as 5% glucose is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion – sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and is a treatment for hypovolaemia.

Figure 13.1 Distribution of water between the vascular and extravascular (interstitial) spaces. This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by ‘suction’ of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.

Table 13.1 Electrolyte composition of intracellular and extracellular fluids (mmol/L)			
	Plasma	Interstitial fluid	Intracellular fluid
Na ⁺	142	144	10
K ⁺	4	4	160
Ca ²⁺	2.5	2.5	1.5
Mg ²⁺	1.0	0.5	13
Cl ⁻	102	114	2
HCO ₃ ⁻	26	30	8
PO ₄ ²⁻	1.0	1.0	57
SO ₄ ²⁻	0.5	0.5	10
Organic acid	3	4	3
Protein	16	0	55

Regulation of extracellular volume (Fig. 13.3)

The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by normal kidneys. Renal Na⁺ excretion varies directly with the effective circulating volume. In a 70 kg man:

- Plasma fluid constitutes one-third of extracellular volume (4.6 L), and of this,
- 85% (3.9 L) lies in the venous side and only 15% (0.7 L) resides in the arterial circulation.

The unifying hypothesis of extracellular volume regulation in health and disease proposed by Schrier states that the fullness of the arterial vascular compartment – or the so-called **effective arterial blood volume (EABV)** – is the primary determinant of renal sodium and water excretion. Thus effective arterial blood volume constitutes **effective circulatory volume** for the purposes of body fluid homeostasis.

The fullness of the arterial compartment depends upon a normal ratio between cardiac output and peripheral arterial resistance. Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree).

Figure 13.2 Relative effects of the addition of 1 L of: (a) water, (b) saline 0.9% and (c) a colloid solution.

When the EABV is expanded, the urinary Na⁺ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na⁺ in the presence of EABV depletion and normal renal function.

These changes in Na⁺ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, it is changes in tubular reabsorption that constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Table 13.2 and Figure 13.4 and Figure 12.2 (see p. 563), which depicts the sites and determinants of segmental Na⁺ reabsorption. Although the loop of Henle and distal tubules make a major overall contribution to net Na⁺ handling, transport in these segments primarily varies with the amount of Na⁺ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na⁺ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts.

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

- **Intrarenal receptors.** Receptors in the walls of the afferent glomerular arterioles respond, via the

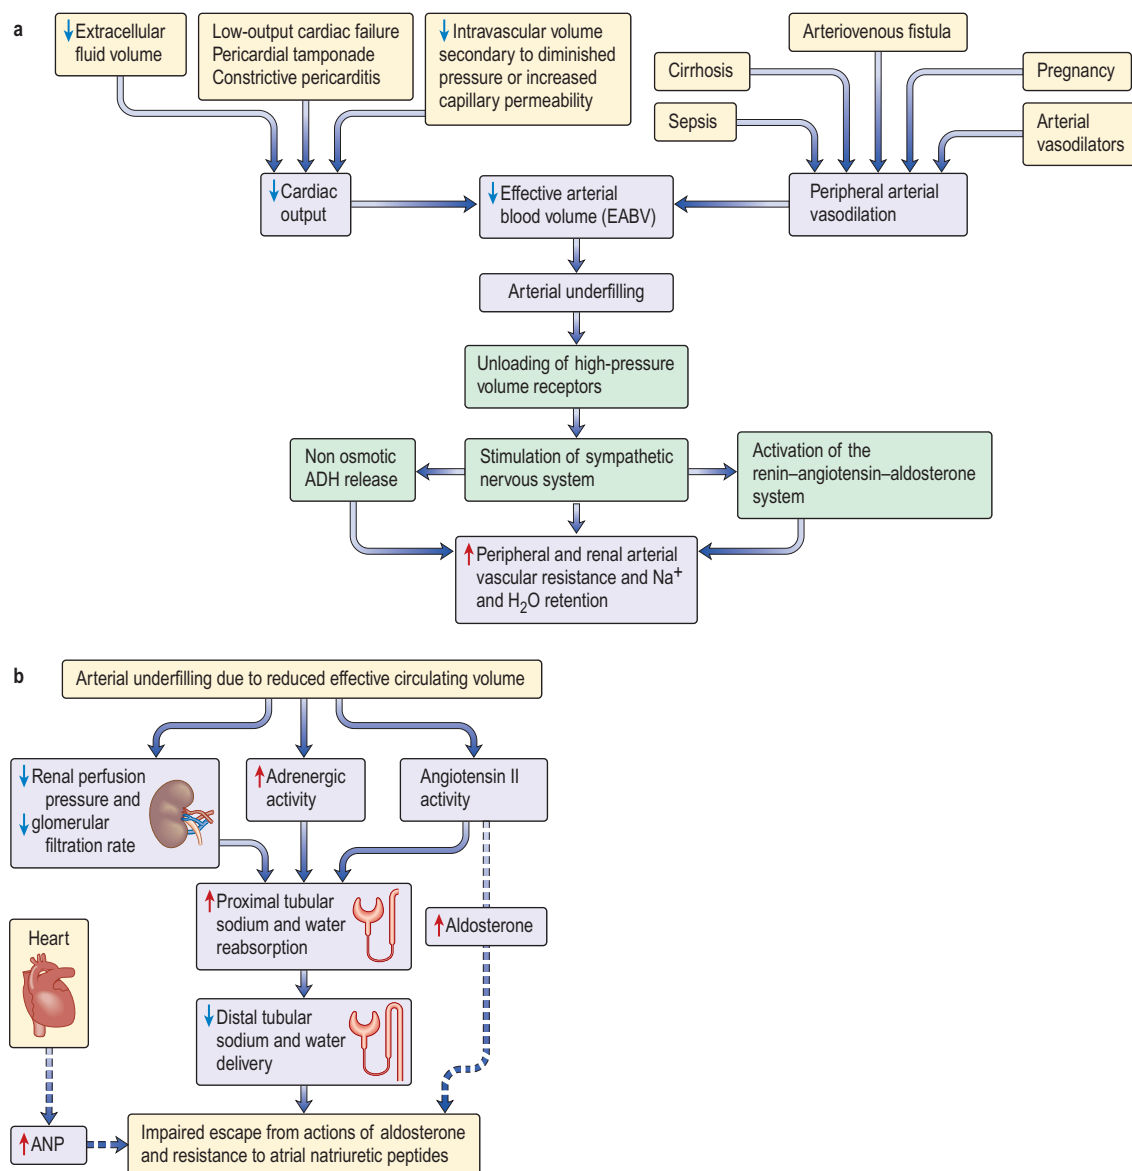

Figure 13.3 Regulation of extracellular volume. (a) Sequence of events in which a decrease in cardiac output or peripheral arterial dilatation initiates renal sodium and water retention. (b) Mechanism of impaired escape from the actions of aldosterone and resistance to atrial natriuretic peptides (ANP). (Modified from Schrier RW. *Renal and Electrolyte Disorders*, 7th edn. Philadelphia: Lippincott Williams and Wilkins; 2010, with permission.)

Table 13.2 Mechanisms of sodium transport in the various nephron segments

	Reabsorbed (%)	Luminal Na ⁺ entry	Transport
Proximal tubule	60–70	Na ⁺ -H ⁺ exchange and cotransport of Na ⁺ with glucose, phosphate and other organic solutes	Angiotensin II Norepinephrine (noradrenaline)
Loop of Henle	20–25	Na ⁺ -K ⁺ -2Cl ⁻ cotransport	Flow dependent Pressure natriuresis mediated by nitric oxide
Distal tubule	5	Na ⁺ -Cl ⁻ cotransport	Flow dependent
Collecting ducts	4	Na ⁺ channels	Aldosterone Atrial natriuretic peptide

juxtaglomerular apparatus, to changes in renal perfusion, and control the activity of the renin-angiotensin-aldosterone system (see p. 1006). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I₂ and E₂ are also generated within the kidney in response to angiotensin II, acting to maintain

glomerular filtration rate and sodium and water excretion, modulating the sodium-retaining effect of this hormone.

- **Extrarenal receptors.** These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective

Figure 13.4 The nephron – electrolyte and water exchange: 180 L of water and 26 000 mmol of sodium/day enter the nephrons via the afferent arterioles to the kidneys. Removal or addition of electrolytes results in the excretion of approximately 1 L of water and 60–180 mmol of sodium/day.

circulating volume and result in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone – atrial natriuretic peptide (ANP) – from granules located in the atrial walls (see p. 943).

High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals. The low-pressure volume receptors are distributed in thoracic tissues (cardiac atria, right ventricle, thoracic veins, pulmonary vessels) and their role in the volume regulatory system is marginal.

Aldosterone and possibly ANP are responsible for day-to-day variations in Na^+ excretion, by their respective ability to augment and diminish Na^+ reabsorption in the collecting ducts.

A *salt load*, for example, leads to an increase in the effective circulatory and extracellular volume, raising both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (see Fig. 12.5), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na^+ reabsorption in the collecting duct, thereby promoting excretion of excess Na^+ .

By contrast, in patients on a *low Na^+* intake or in those who become volume-depleted as a result of vomiting and diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin-angiotensin-aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na^+ reabsorption in the collecting ducts, leading to a fall in Na^+ excretion. This increases the extracellular volume towards normal.

With more marked hypovolaemia, a decrease in GFR leads to an increase in proximal and thin ascending limb Na^+ reabsorption which contributes to Na^+ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 13.3b) and non-osmotic release of antidiuretic hormone (ADH), also called vasopressin. The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process is partly mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production.

Volume regulation in oedematous conditions

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here the principal mediator of salt and water retention is the concept of arterial underfilling due either to reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. ‘unloading’ of arterial volume receptors), which results in activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system and non-osmotic release of ADH. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume. The common nature of the degree of arterial fullness and neurohumoral pathway in the regulation of extracellular volume in health and disease states forms the basis of Schrier’s unifying hypothesis of volume homeostasis (Fig. 13.3a).

Mechanism of impaired escape from actions of aldosterone and resistance to ANP

Not only is the activity of the renin-angiotensin-aldosterone system increased in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with Conn’s syndrome, who have increased aldosterone secretion (see p. 989).

In normal subjects, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5–2 L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism (Conn’s syndrome). The escape is dependent on an increase in delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery which overwhelms the sodium-retaining actions of aldosterone.

In patients with the above oedematous conditions, e.g. heart failure, escape from the sodium-retaining actions of aldosterone **does not occur** and therefore they continue to retain sodium in response to aldosterone. Accordingly they have substantial natriuresis when given spironolactone,

which blocks mineralocorticoid receptors. Alpha-adrenergic stimulation and elevated angiotensin II increase sodium transport in the proximal tubule, and reduced renal perfusion and GFR further increases sodium absorption from the proximal tubules by presenting less sodium and water in the tubular fluid. Sodium delivery to the distal portion of the nephron, and thus the collecting duct, is reduced. Similarly, increased cardiac ANP release in these conditions requires optimum sodium concentration at the site of its action in the collecting duct for its desired natriuretic effects. Decreased sodium delivery to the collecting duct is therefore the most likely explanation for the persistent aldosterone-mediated sodium retention, absence of escape phenomenon and resistance to natriuretic peptides in these patients (Fig. 13.3b).

Regulation of water excretion

Body water homeostasis is affected by thirst and the urine concentrating and diluting functions of the kidney. These in turn are controlled by intracellular osmoreceptors, principally in the hypothalamus, to some extent by volume receptors in capacitance vessels close to the heart, and via the renin-angiotensin system. Of these, the major and best-understood control is via osmoreceptors. Changes in the plasma Na^+ concentration and osmolality are sensed by osmoreceptors that influence both thirst and the release of ADH (vasopressin) from the supraoptic and paraventricular nuclei of the anterior hypothalamus.

ADH plays a central role in urinary concentration by increasing the water permeability of the normally impermeable cortical and medullary collecting ducts. There are three major G-protein coupled receptors for vasopressin (ADH):

- V_{1A} found in vascular smooth muscle cells
- V_{1B} in anterior pituitary and throughout the brain
- V_2 receptors in the principal cells of the kidney distal convoluting tubule and collecting ducts (see below).

Activation of the V_{1A} receptors induces vasoconstriction while V_{1B} receptors appear to mediate the effect of ADH on the pituitary, facilitating the release of ACTH. The V_2 receptors mediate the antidiuretic response as well as other functions.

The ability of ADH to increase the urine osmolality is related indirectly to transport in the ascending limb of the loop of Henle, which reabsorbs NaCl without water. This process, which is the primary step in the countercurrent mechanism, has two effects: it makes the tubular fluid dilute and the medullary interstitium concentrated. In the absence of ADH, little water is reabsorbed in the collecting ducts, and a dilute urine is excreted. By contrast, the presence of ADH promotes water reabsorption in the collecting ducts down the favourable osmotic gradient between the tubular fluid and the more concentrated interstitium. As a result, there is an increase in urine osmolality and a decrease in urine volume.

The cortical collecting duct has two cell types (see also p. 597) with very different functions:

- **Principal cells** (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na^+/K^+ -ATPase pumps in the basolateral membrane.
- **Intercalated cells**, in comparison, do not transport NaCl (since they have a lower level of Na^+/K^+ -ATPase activity) but play a role in hydrogen and bicarbonate handling and in potassium reabsorption in states of potassium depletion.

The ADH-induced increase in collecting duct water permeability occurs primarily in the principal cells. ADH acts on V_2 (vasopressin) receptors located on the basolateral surface of principal cells, resulting in the activation of adenylyl cyclase. This leads to protein kinase activation and to preformed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to and then being inserted into the luminal membrane. Four renal aquaporins have been well characterized and are localized in different areas of the cells of the collecting duct. The water channels span the luminal membrane and permit water movement into the cells down a favourable osmotic gradient (Fig. 13.5). This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the ADH effect has worn off, the water channels aggregate within clathrin-coated pits, from which they are removed from the luminal membrane by endocytosis and returned to the cytoplasm. A defect in any step in this pathway, such as in attachment of ADH to its receptor or the function of the water channel, can cause resistance to the action of ADH and an increase in urine output. This disorder is called *nephrogenic diabetes insipidus*.

Plasma osmolality

In addition to influencing the rate of water excretion, ADH plays a central role in osmoregulation because its release is directly affected by the plasma osmolality. At a plasma osmolality of <275 mosmol/kg, which usually represents a plasma Na^+ concentration of <135 – 137 mmol/L, there is essentially no circulating ADH. As the plasma osmolality rises above this threshold, however, the secretion of ADH increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na^+ concentration is normally maintained within 1–2% of its baseline value.

1. **Ingestion of a water load** leads to an initial reduction in the plasma osmolality, thereby diminishing the release of ADH. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine.

Figure 13.5 Aquaporin-mediated water transport in the renal collecting duct. Stimulation of the vasopressin 2 receptor causes cAMP-mediated insertion of the aquaporin 2 into the apical membrane, allowing water transport down the osmotic gradient. (Adapted from Connolly DL, Shanahan CM, Weissberg PL. Water channels in health and disease. Lancet 1996; 347:211, with permission from Elsevier.)

2. **Water loss** resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hypernatraemic, because urinary water loss is offset by the thirst mechanism.

Osmoregulation versus volume regulation

A common misconception is that regulation of the plasma Na^+ concentration is closely correlated with the regulation of Na^+ excretion. However, it is related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- **A water load** is rapidly excreted (in 4–6 h) by inhibition of ADH release so that there is little or no water reabsorption in the collecting ducts. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin-angiotensin-aldosterone system. Thus, a dilute urine is excreted, and there is little alteration in the excretion of Na^+ .
- **0.9% saline** administration, by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na^+ in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered and both pathways are activated. For example, if a person with normal renal function eats salted potato chips and peanuts without drinking any water, the excess Na^+ will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na^+ without water.

This principle of separate volume and osmoregulatory pathways is also evident in the **syndrome of inappropriate ADH secretion (SIADH)**. Patients with SIADH (see p. 993) have impaired water excretion and hyponatraemia (dilutional) caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na^+ handling remains intact. These findings have implications for the correction of the hyponatraemia in this setting which initially requires restriction of water intake.

ADH is also secreted by non-osmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (e.g. cardiac failure, hepatic cirrhosis), psychiatric disturbance and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic

overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of V_{1A} (vasopressin) receptors distributed in the vascular smooth muscle cells.

Regulation of cell volume

Most cells respond to swelling or shrinkage by activating specific metabolic or membrane-transport processes that return cell volume to its normal resting state. Within minutes after exposure to hypotonic solutions and resulting cell swelling, a common feature of many cells is the increase in plasma membrane potassium and chloride conductance. Although extrusion of intracellular potassium certainly contributes to a regulatory volume decrease, the role of chloride efflux itself is modest, given the relatively low intracellular chloride concentration. Other intracellular osmolytes, such as taurine and other amino acids, are transported out of the cell to achieve a regulatory volume decrease. By contrast, these regulatory mechanisms are operative in reverse to protect cell volume under hypertonic conditions, as is the case in the renal medulla. The tubular cells at the tip of renal papillae, which are constantly exposed to a hypertonic extracellular milieu, maintain their cell volume on a long-term basis by actively taking up smaller molecules, such as betaine, taurine and myoinositol, and by synthesizing more sorbitol and glycerophosphocholine.

Increased extracellular volume

Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- Venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- Capillary permeability
- Oncotic pressure – mainly dependent on serum albumin
- Lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume or both.

Clinical features

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected, although they may be spared in patients with lipodermatosclerosis (where the skin is tethered and cannot expand to accommodate the oedema). Oedema may be noted in the face, particularly in the morning. In a patient in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusion, pericardial effusion and ascites. Expansion of the blood volume (overload) causes a raised jugular venous pressure, cardiomegaly, added heart sounds, basal crackles as well as a raised arterial blood pressure in certain circumstances.

Causes

Extracellular volume expansion is due to sodium chloride retention. Increased oral salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms which increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume

expansion. Most causes of extracellular volume expansion are associated with renal sodium chloride retention.

Heart failure

Reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to activation of the renin-angiotensin-aldosterone system, non-osmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (Fig. 13.3a). Sympathetic overdrive also indirectly augments ADH and renin-angiotensin-aldosterone response in these conditions. The cumulative effect of these mediators results in increased peripheral and renal arteriolar resistance and water and sodium retention. These factors result in extracellular volume expansion and increased venous pressure, causing oedema formation.

Hepatic cirrhosis

The mechanism is complex, but involves peripheral vasodilatation (possibly owing to increased nitric oxide generation) resulting in reduced effective arterial blood volume (EABV) and arterial filling. This leads to an activation of a chain of events common to cardiac failure and other conditions with marked peripheral vasodilatation (Fig. 13.3). The cumulative effect results in increased peripheral and renal resistance, water and sodium retention, and oedema formation.

Nephrotic syndrome

Interstitial oedema is a common clinical finding with hypoalbuminaemia, particularly in the nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium output, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD) where Na^+/K^+ -ATPase expression and activity are increased threefold along the basolateral surface (Fig. 13.4). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is altered in patients with nephrotic syndrome by enhanced *kidney specific* catabolism of cyclic GMP (the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in the plasma oncotic pressure and the subsequent increase in the transcapillary oncotic gradient. However, the oncotic pressure and transcapillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered. Conversely, capillary hydraulic conductivity (a measure of permeability) is increased. This is determined by intercellular macromolecular complexes between the endothelial cells consisting of tight junctions (made of occludins, claudins and ZO proteins) and adherens junctions (made of cadherin, catenins and actin cytoskeleton). Elevated $\text{TNF-}\alpha$ levels in nephrotic syndrome activate protein kinase C, which changes phosphorylation of occludin and capillary permeability. In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the consequent fall in cardiac output and arterial filling can lead to a chain of events as in cardiac failure and cirrhosis (see above and Fig. 13.3). These factors result in extracellular volume expansion and oedema formation.

Sodium retention

A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see p. 582), or may occur as part of the presentation of chronic kidney disease. In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs cause renal sodium retention, particularly in patients whose renal function is already impaired:

- **Oestrogens** cause mild sodium retention, due to a weak aldosterone-like effect. This is the cause of weight gain in the premenstrual phase.
- **Mineralocorticoids and liquorice** (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- **NSAIDs** cause sodium retention in the presence of activation of the renin-angiotensin-aldosterone system by heart failure, cirrhosis and in renal artery stenosis.
- **Thiazolidinediones (TZD)** (see p. 1011) are widely used to treat type 2 diabetes. Their mechanism of action is attributed to binding and activation of the PPAR- γ system. PPARs are nuclear transcription factors essential to the control of energy metabolism that are modulated via binding with tissue-specific fatty acid metabolites. Of the three PPAR isoforms, γ has been extensively studied and is expressed at high levels in adipose and liver tissues, macrophages, pancreatic- β cells and principal cells of the collecting duct. These drugs have been associated with salt and water retention and are contraindicated in patients with heart failure. Recent evidence suggests that TZD-induced oedema (like insulin) is also due to upregulation of epithelial Na transporter channel (ENaC) but by different pathways. Diuretics of choice for TZD-induced oedema are amiloride and triamterene.

Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as 'third spaces'. Bone may also act as a 'sink' for sodium and water.

Other causes of oedema

- Initiation of insulin treatment for type 1 diabetes and refeeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex but involves upregulation of ENaC in the principal cell of the collecting duct. This transporter is amiloride sensitive which makes amiloride or triamterene the diuretic of choice in insulin-induced oedema.
- Oedema may result from increased capillary pressure owing to relaxation of precapillary arterioles. The best example is the peripheral oedema caused by dihydropyridine calcium-channel blockers such as nifedipine which affects up to 10% of the patients. Oedema is usually resolved by stopping the offending drug.
- Oedema is also caused by increased interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (see p. 981).

Idiopathic oedema of women

This, by definition, occurs in women without heart failure, hypoalbuminaemia, renal or endocrine disease. Oedema is intermittent and often worse in the premenstrual phase. The condition remits after the menopause. Patients complain of swelling of the face, hands, breasts and thighs, and a feeling of being bloated. Sodium retention during the day and increased sodium excretion during recumbency are characteristic; an abnormal fall in plasma volume on standing caused by increased capillary permeability to proteins may be the cause of this. The oedema may respond to diuretics, but returns when they are stopped. A similar syndrome of diuretic-dependent sodium retention can be caused by abuse of diuretics, for instance as part of an attempt to lose weight; but not all women with idiopathic oedema admit to having taken diuretics, and the syndrome was described before diuretics were introduced for clinical use, so the cause remains unclear.

Local increase in oedema

This does not reflect disturbances of extracellular volume control per se, but can cause clinical confusion. Examples are ankle oedema due to venous damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction.

Treatment

The underlying cause should be treated where possible. Heart failure, for example, should be treated, and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role, but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manoeuvres that increase venous return (e.g. strict bed rest or water immersion) stimulate salt and water excretion

by effects on cardiac output and ANP release, but they are seldom of practical value.

The *mainstay of treatment is the use of diuretic agents*, which increase sodium, chloride and water excretion in the kidney (Table 13.3). These agents act by interfering with membrane ion pumps which are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

Clinical use of diuretics

Loop diuretics

These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium-potassium-2-chloride (NKCC2) channel in the thick ascending limb of Henle (Fig. 13.6) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Unwanted effects include:

- Urate retention causing gout
- Hypokalaemia
- Hypomagnesaemia
- Decreased glucose tolerance
- Allergic tubulointerstitial nephritis and other allergic reactions
- Myalgia – especially with high-dose bumetanide
- Ototoxicity (due to an action on sodium pump activity in the inner ear) – particularly with furosemide
- Interference with excretion of lithium, resulting in toxicity.

There is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and

Table 13.3 Types and clinical uses of diuretics

Class	Major action	Examples	Clinical uses	Potency
Loop diuretics	↓ Na ⁺ -Cl ⁻ -K ⁺ cotransport in thick ascending limb of loop of Henle	Furosemide Bumetanide Torsemide	Volume overload (CCF, nephrotic syndrome, CKD) ?Acute kidney injury SIADH	+++
Thiazide and related diuretics	↓ Na ⁺ -Cl cotransport in early distal convoluted tubule	Bendroflumethiazide Chlorthalidone Metolazone Indapamide	Hypertension Volume overload (CCF) Hypercalciuria	++
Potassium sparing	↓ Na ⁺ reabsorption (in exchange for K ⁺) in collecting duct (principal cells)	Aldosterone antagonists, e.g. spironolactone, eplerenone Others: amiloride, triamterene	Hyperaldosteronism (primary and secondary) Bartter's syndrome Heart failure Cirrhosis with fluid overload Prevention of K ⁺ deficiency in combination with loop or thiazide	+
Carbonic anhydrase inhibitors	↓ Na ⁺ HCO ₃ ⁻ reabsorption in proximal collecting duct ↓ Aqueous humour formation	Acetazolamide	Metabolic alkalosis Glaucoma	±
Vasopressin/ADH receptor blockers (aquaretics)	Block V ₂ receptor in collecting ducts producing free water diuresis	Lixivaptan Tolvaptan Satavaptan Conivaptan	Heart failure, cirrhosis, SIADH	+

CCF, congestive cardiac failure; CKD, chronic kidney disease; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Figure 13.6 Transport mechanisms in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed in the thick ascending limb by the *bumetanide-sensitive* sodium-potassium-2-chloride cotransporter (NKCC2). The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+ -ATPase and the kidney-specific basolateral chloride channel (CIC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (ROMK – renal outer medulla K^+ channel) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential. Genetic studies have identified putative loss of function mutations in the genes encoding NKCC2 1, ROMK 2, CIC-Kb 3, and barttin 4 in subgroups of patients with **Barter's syndrome**. In contrast to the normal condition, loss of function of NKCC2 impairs reabsorption of sodium and potassium. Inactivation of the basolateral CIC-Kb and *barttin* reduces transcellular reabsorption of chloride. Loss of function of any of these will reduce the transepithelial potential and thus decrease the driving force for the paracellular reabsorption of cations (K^+ , Mg^{2+} , Ca^{2+} and Na^+). Paracellin-1 is necessary for the paracellular transport of Ca^{2+} and Mg^{2+} . In most patients with **Barter's syndrome**, urinary calcium excretion is increased. Hypercalcaemia or increased activation of calcium-sensing receptor inactivates ROMK and causes Barter's syndrome. Ka and Kb, kidney-specific basolateral chloride channel. ROMK, renal outer medullary potassium channel.

has more beneficial effects than furosemide on venous capacitance in left ventricular failure.

Thiazide diuretics (see p. 719)

These are less potent than loop diuretics. They act by blocking a sodium chloride channel in the *distal convoluted tubule* (Fig. 13.7). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria, but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for

Figure 13.7 Transport mechanisms in the distal convoluted tubule. Under normal conditions, sodium chloride is reabsorbed by the apical *thiazide-sensitive* sodium-chloride cotransporter (NCCT) in the distal convoluted tubule. The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na^+/K^+ -ATPase and an, as yet, undefined basolateral chloride channel. In this nephron segment, there is an apical calcium channel and a basolateral sodium-coupled exchanger. Physiological evidence indicates that the mechanisms for the transport of magnesium are similar to those for calcium. In **Gitelman's syndrome**, putative loss of function mutations in the sodium-chloride cotransporter (NCCT (X)) lead to decreased reabsorption of sodium chloride and increased reabsorption of calcium. Functional overactivity of NCCT leads to **Gordon's syndrome** by a new mechanism (see text). TRPM6, a member of the transient receptor potential family.

its action on glomerular filtration, and therefore retains its potency in renal impairment.

Potassium-sparing diuretics (see Fig. 13.8)

These are of two types.

- **Aldosterone antagonists**, which compete with aldosterone in the *collecting ducts* and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these patients by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone is devoid of antiandrogenic or antiprogesterone properties.
- **Amiloride and triamterene** inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium-sparing agents with thiazide or loop diuretics.

Carbonic anhydrase inhibitors

These are relatively weak diuretics and are seldom used except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia.

Aquaretics (vasopressin or antidiuretic hormone antagonists)

Vasopressin V_2 receptor antagonists are very useful agents in the treatment of conditions associated with elevated levels

of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 993). Non-peptide vasopressin V₂ receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction (see p. 650).

Resistance to diuretics

Resistance may occur as a result of:

- Poor bioavailability
- Reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
- Activation of sodium-retaining mechanisms, particularly aldosterone.

Management. Intravenous administration of diuretics may establish a diuresis. High doses of loop diuretics are required to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 2 g for an adult, because of ototoxicity. Intravenous albumin solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and allow mobilization of oedema but do not increase the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure, because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance. Both aminophylline and dopamine increase renal blood flow and may be useful in refractory cardiogenic sodium retention. In addition, theophyllines, by inhibiting phosphodiesterase activity in the inner medullary collecting duct, prolong the action of cyclic GMP (a second messenger of ANP).

Effects on renal function

All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations diuretics also decrease GFR:

- Excessive diuresis causes volume depletion and prerenal failure
- Diuretics can cause allergic tubulointerstitial nephritis
- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume and may have profound effects on organ function.

Clinical features

Symptoms. Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

- **Loss of interstitial fluid** leads to loss of skin elasticity ('turgor') – the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the forehead is a very useful sign in all ages.
- **Loss of circulating volume** leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs.

Loss of more than this causes the following:

Postural hypotension

Normally the blood pressure rises if a subject stands up, as a result of increased venous return due to venoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Table 13.4).

Low jugular venous pressure

In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH₂O.

Peripheral venoconstriction

This causes cold skin with empty peripheral veins, which are difficult to cannulate just when the patient needs intravenous therapy the most! This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

Tachycardia

This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

Causes

Salt and water may be lost from the kidneys, from the gastrointestinal tract, or from the skin. Examples are given in Table 13.5.

Table 13.4 Postural hypotension: some causes of a fall in blood pressure from lying to standing

Decreased circulating volume (hypovolaemia)**Autonomic failure**

Ageing

Interference with autonomic function by drugs

Ganglion blockers
Tricyclic antidepressants
Interference with peripheral vasoconstriction by drugs
Nitrates
Calcium-channel blockers
α-Adrenoreceptor blocking drugs

Prolonged bed rest (cardiovascular deconditioning)

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water.

- Septicaemia causes vasodilatation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic).

Investigations

Blood tests are in general not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to prerenal failure (when the creatinine rises as well), but this is very nonspecific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in volume depletion (owing to increased water reabsorption), but may also often mislead.

Assessment of volume status is shown in [Box 13.1](#).

Treatment

The overriding principle is to replace what is missing.

Haemorrhage

The rational treatment of acute haemorrhage is the infusion of a combination of red cells and a plasma substitute or (if unavailable) whole blood. (Chronic anaemia causes salt and

water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilatation.)

Loss of plasma

Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see [p. 390](#)).

Loss of water and electrolytes

Loss of water and electrolytes, as occurs with vomiting, diarrhoea, or excessive renal losses, should be treated by replacement of the loss. If possible, this should be with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol each of Na^+ and Cl^- per tablet), the usual dose of which is 6–12 tablets/day with 2–3 L of water. It is used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodium bicarbonate (500 mg, 6 mmol each of Na^+ and HCO_3^- per tablet) is used in doses of 6–12 tablets/day with 2–3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. chronic kidney disease, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance. Oral rehydration solutions are described in [Box 4.10](#).

Intravenous fluids are sometimes required ([Table 13.6](#)). Rapid infusion (e.g. 1000 mL per hour or even faster) is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion); in these situations, plasma expanders (colloids) are often used in the first instance to restore an adequate circulating volume (see [p. 887](#)). Repeated clinical assessments are vital in this situation, usually complemented by frequent measurements of central venous pressure (see [p. 872](#), for the management of shock). Severe hypovolaemia induces vasoconstriction, which maintains venous return; over-rapid correction does not give time

Table 13.5 Causes of extracellular volume depletion

Haemorrhage	Renal losses
External	Diuretic use
Concealed, e.g. leaking aortic aneurysm	Impaired tubular sodium conservation
Burns	Reflux nephropathy
Gastrointestinal losses	Papillary necrosis
Vomiting	Analgesic nephropathy
Diarrhoea	Diabetes mellitus
Ileostomy losses	Sickle cell disease
Ileus	

Box 13.1 Assessment of volume status

Best achieved by simple clinical observations which you should do yourself. Check:

- Jugular venous pressure
- Central venous pressure both basal and after intravenous fluid challenge ([p. 873](#))
- Postural changes in blood pressure
- A chest X-ray
- Serial weights of the patient
- Urine output measurements at regular intervals

Table 13.6 Intravenous fluids in general use for fluid and electrolyte disturbances

	Na^+ (mmol/L)	K^+ (mmol/L)	HCO_3^- (mmol/L)	Cl^- (mmol/L)	Indication ^{a-d}
Normal plasma values	142	4.5	26	103	
Sodium chloride 0.9%	150	–	–	150	1
Sodium chloride 0.18% + glucose 4%	30	–	–	30	2
Glucose 5% + potassium chloride 0.3%	–	40	–	40	3
Sodium bicarbonate 1.26%	150	–	150	–	4

^a1, Volume expansion in hypovolaemic patients. Rarely to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20–40 mmol/L.

^b2, Maintenance of fluid balance in normovolaemic, normonatraemic patients.

^c3, To replace water. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).

^d4, For volume expansion in hypovolaemic, acidotic patients alternating with (1). Occasionally for maintenance of fluid balance combined with (2) in salt-wasting, acidotic patients.

for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema) even if a total body extracellular fluid (ECF) deficit remains. In less severe ECF depletion (such as in a patient with postural hypotension complicating acute tubular necrosis), the fluid should be replaced at a rate of 1000 mL every 4–6 h, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1–2 L can be given over 24 h, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, bodyweight and plasma biochemistry is mandatory.

Loss of water alone

This causes extracellular volume depletion only in severe cases, because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (e.g. after surgery), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% glucose with K⁺, because pure water would lead to osmotic lysis of blood cells.

DISORDERS OF SODIUM CONCENTRATION

These are best thought of as disorders of body water content. As discussed above, sodium content is regulated by volume receptors; water content is adjusted to maintain, in health, a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

Hyponatraemia

Hyponatraemia (Na <135 mmol/L) is a common biochemical abnormality. The causes depend on the associated changes in extracellular volume:

- Hyponatraemia with hypovolaemia (Table 13.7)
- Hyponatraemia with euvolaemia (Table 13.8)
- Hyponatraemia with hypervolaemia (Table 13.9).

Rarely, hyponatraemia may be a 'pseudo-hyponatraemia'. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being

confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of 'hyponatraemia' is unnecessary. *Note:* Artefactual 'hyponatraemia', caused by taking blood from the limb into which fluid of low sodium concentration is being infused, should be excluded.

Hyponatraemia with hypovolaemia

This is due to salt loss in excess of water loss; the causes are listed in Table 13.7. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors); but as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing <10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

Clinical features

With sodium depletion the clinical picture is usually dominated by features of volume depletion (see p. 638). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality.

Table 13.10 shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adrenocortical disease may be less easily identified but a urinary sodium

Table 13.8 Causes of hyponatraemia with normal extracellular volume (euvolaemia)

Diarrhoea	130	10–30	95	1000–2000+

concentration of >20 mmol/L, in the presence of clinically evident volume depletion, suggests a renal loss.

Treatment

This is directed at the primary cause whenever possible. In a healthy patient:

- Give oral electrolyte-glucose mixtures (see p. 122)
- Increase salt intake with slow sodium 60–80 mmol/day.

In a patient with vomiting or severe volume depletion:

- Give intravenous fluid with potassium supplements, i.e. 1.5–2 L 5% glucose (with 20 mmol K⁺) and 1 L 0.9% saline over 24 h PLUS measurable losses
- Correction of acid–base abnormalities is usually not required.

Hyponatraemia with euvolaemia

(see Table 13.8)

This results from an intake of water in excess of the kidney's ability to excrete it (dilutional hyponatraemia) with no change in body sodium content but the plasma osmolality is low.

- With normal kidney function, dilution hyponatraemia is uncommon even if a patient drinks approximately 1 L per hour.
- The most common iatrogenic cause is overgenerous infusion of 5% glucose into postoperative patients; in this situation it is exacerbated by an increased ADH secretion in response to stress.
- Postoperative hyponatraemia is a common clinical problem (almost 1% of patients) with *symptomatic* hyponatraemia occurring in 20% of these patients.
- Marathon runners drinking excess water and 'sports drinks' can become hyponatraemic.
- Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males.

To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer 0.9% saline unless otherwise clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.

Some degree of hyponatraemia is usual in acute oliguric kidney injury, while in chronic kidney disease (CKD) it is most often due to ill-given advice to 'push' fluids.

Clinical features

Dilutional hyponatraemia symptoms are common when hyponatraemia develops *acutely* (<48 h, often postoperatively). Symptoms rarely occur until the serum sodium is less than 120 mmol/L and are more usually associated with values around 110 mmol/L or lower, particularly when

chronic. They are principally neurological and are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy symptoms and signs include headache, confusion and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions and eventually coma. MRI scan of the brain reveals cerebral oedema but, in the context of electrolyte abnormalities and neurological symptoms, it can help to make a confirmatory diagnosis.

Risk factors for developing hyponatraemic encephalopathy. The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors rather than the absolute change in serum sodium predict whether a patient will suffer hyponatraemic encephalopathy.

- **Children** under 16 years are at increased risk due to their relatively larger brain-to-intracranial volume ratio compared with adults.
- **Premenopausal women** are more likely to develop encephalopathy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation resulting in vasoconstriction and hypoperfusion of brain.
- **Hypoxaemia** is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia, who develop hypoxia due to either non-cardiac pulmonary oedema or hypercapnic respiratory failure, have a high risk of mortality. Hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations

The cause of hyponatraemia with apparently normal extracellular volume requires investigation:

- Plasma and urine electrolytes and osmolalities. The plasma concentrations of sodium, chloride and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality. However, maximal dilution (<50 mosmol/kg) is not always present.
- Further investigations to exclude Addison's disease, hypothyroidism, 'syndrome of inappropriate ADH secretion' (SIADH) and drug-induced water retention, e.g. chlorpropamide.

Remember, potassium and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia.

The syndrome of inappropriate ADH secretion is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release – an example is chronic alcohol use.

Treatment

The underlying cause should be corrected where possible.

- Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL/day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly (1 L over 12 hours) is sufficient.
- **Acute onset with symptoms.** The most common cause of acute hyponatraemia in adults is postoperative iatrogenic hyponatraemia. Excessive water intake associated with psychosis, marathon running and use of Ecstasy (a recreational drug) are other causes. All are acute medical emergencies and should be treated aggressively and immediately. In patients in whom there are severe neurological signs, such as fits or coma or cerebral oedema, *hypertonic saline* (3%, 513 mmol/L) should be used. It must be given very slowly (not more than 70 mmol/h), the aim being to increase the serum sodium by 4–6 mmol/L in the first 4 hours, but the absolute change should not exceed 15–20 mmol/L over 48 hours.

In general, the plasma sodium should not be corrected to >125–130 mmol/L. 1 mL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L, assuming that total body water comprises 50% of total bodyweight.

- **Symptomatic hyponatraemia in patients with intracranial pathology** should be managed aggressively and immediately with 3% saline like acute hyponatraemia.
- **Chronic/asymptomatic.** If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality and the hyponatraemia can be corrected slowly (without use of hypertonic saline).

However, clinically it can be difficult to know how long the hyponatraemia has been present and 3% of hypertonic saline is still required.

Osmotic demyelination syndrome (ODS)

Avoiding ODS

A rapid rise in extracellular osmolality, particularly if there is an 'overshoot' to high serum sodium and osmolality, will result in the osmotic demyelination, syndrome (ODS), formally known as central pontine demyelination, which is a devastating neurologic complication. Plasma sodium concentration in patients with hyponatraemia should not rise by more than 8 mmol/L per day. The rate of rise of plasma sodium should be even lower in patients at higher risk for ODS, e.g. patients with alcohol excess, cirrhosis, malnutrition, or hypokalaemia. Other factors predisposing to demyelination are pre-existing hypoxaemia and CNS radiation (see above). ODS is diagnosed by the appearance of characteristic hypointense lesions on T₁-weighted images and hyperintense on T₂-weighted images on MRI; these take up to 2 weeks or longer to appear.

The pathophysiology of ODS is not fully understood. The most plausible explanation is that the brain loses organic osmolytes very quickly in order to adapt to hyponatraemia so that osmolality is similar between the intracellular and extracellular compartments. However, neurones reclaim

organic osmolytes slowly in the phase of rapid correction of hyponatraemia, resulting in an hypo-osmolar intracellular compartment and lead to shrinkage of cerebral vascular endothelial cells. Consequently the blood–brain barrier is functionally impaired, allowing lymphocytes, complement, and cytokines to enter the brain, damage oligodendrocytes, activate microglial cells and cause demyelination.

The most crucial issue in the treatment of hyponatraemia is to prevent **rapid correction**. A rapid rise in plasma sodium is almost always due to a water diuresis, which happens when vasopressin (ADH) action stops suddenly, for example with volume repletion in patients with intravascular volume depletion, cortisol replacement in patients with Addison disease, resolution of non-osmotic stimuli for vasopressin release such as nausea or pain. However, sometimes chronic hyponatraemia can develop in the absence of vasopressin excess. Even in these cases, water diuresis due to **increased distal delivery of filtrate** is the main cause of rapid rise in plasma sodium.

In the absence of vasopressin, *it is generally assumed that* the total urine volume is equal to the volume of filtrate delivered to the distal nephron, which is the GFR minus the volume reabsorbed in the proximal convoluted tubule (PCT). Approximately 80% of the GFR is reabsorbed in PCT under normal circumstance (increases even more in the presence of intravascular volume depletion). However, *in real life* water excretion will be less than the volume of distal delivery of filtrate, even in the absence of vasopressin, because a significant degree of water is reabsorbed in the inner medullary collecting duct through its residual water permeability, prompted by a very high osmotic force in the interstitium (see Fig. 12.2).

Even a modest water diuresis in the elderly with reduced muscle mass is large enough to cause a rapid rise in plasma sodium. Moreover, there is a higher risk for ODS if hypokalaemia is present. In such cases if plasma sodium rises too quickly due to anticipated water diuresis, administration of desmopressin to stop the water diuresis is beneficial. If plasma sodium rises regardless then lowering plasma sodium to the maximum limit of correction (<8 mmol/L per day) with the administration of 5% glucose solution is the best strategy.

Reversible hyponatraemia culminating in hyponatraemia

In many patients, the cause of water retention is reversible (e.g. hypovolaemia, thiazide diuretics). On correction of the cause, vasopressin levels fall and plasma sodium rises by up to 2 mmol/L per hour as a result of excretion of dilute urine. This excessive water diuresis should be anticipated and prevented by use of desmopressin.

Patients who are chronically hyponatraemic with concomitant hypokalaemia are especially susceptible to overcorrection. Plasma sodium is a function of the ratio of exchangeable body sodium plus potassium to total body water, so potassium administration increases sodium concentration. For example, a mildly symptomatic hyponatraemic patient with a plasma sodium of <120 mmol/L and potassium of <2 mmol/L can potentially develop ODS as a result of overcorrection of hyponatraemia simply as a direct result of replacing the large potassium deficit.

Antidiuretic hormone antagonists (vasopressin antagonists)

Vasopressin V₂ receptor antagonists (see p. 645), which produce a free water diuresis, are being used in clinical trials

for the treatment of hyponatraemic encephalopathy. Three oral agents, lixivaptan, tolvaptan and satavaptan, are selective for the V_2 (antidiuretic) receptor, while conivaptan blocks both the V_{1A} and V_2 receptors.

These agents produce a selective water diuresis without affecting sodium and potassium excretion; they raise the plasma sodium concentration in patients with hyponatraemia caused by the SIADH, heart failure and cirrhosis.

The efficacy of oral tolvaptan in ambulatory patients has been demonstrated in patients with hyponatraemia (mean plasma sodium 129 mmol/L) caused by the SIADH, heart failure, or cirrhosis who had a sustained rise in plasma sodium to 136 mmol/L for 4 weeks. Tolvaptan is now approved for use in patients with euvoalaemic hyponatraemia and those with SIADH. In addition, intravenous conivaptan is available and is also approved for the treatment of euvoalaemic hyponatraemia (i.e. SIADH) in some countries. The approved dosing for conivaptan is a 20 mg bolus followed by continuous infusion of 20 mg over 1–4 days. The continuous infusion increases the risk of phlebitis, which requires the use of large veins and changing the infusion site every 24 hours.

Hyponatraemia with hypervolaemia

The common causes of hyponatraemia due to water excess are shown in Table 13.9. In all these conditions, there is usually an element of reduced glomerular filtration rate with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the 'diluting' ascending limb of Henle's loop and a reduced ability to generate 'free water', with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in Henle's loop (loop diuretics) or distally (thiazides).

Syndrome of inappropriate ADH secretion

This is described in Chapter 19 (p. 746). There is inappropriate secretion of ADH, causing water retention and hyponatraemia.

Hypernatraemia

This is much rarer than hyponatraemia and nearly always indicates a water deficit. Causes are listed in Table 13.11).

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the above cause hypernatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

Clinical features

Symptoms of hypernatraemia are nonspecific. Nausea, vomiting, fever and confusion may occur. A history of long-standing polyuria, polydipsia and thirst suggests diabetes insipidus. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Table 13.11 Causes of hypernatraemia

ADH deficiency	Osmotic diuresis
Pituitary diabetes insipidus (see p. 992)	Total parenteral nutrition
Isotonic	Hyperosmolar hyperglycaemic state (see p. 1020)
Administration of hypertonic sodium solutions	PLUS
Administration of drugs with a high sodium content (e.g. piperacillin)	Deficient water intake: impaired thirst or consciousness
Use of 8.4% sodium bicarbonate after cardiac arrest.	Excessive water loss through skin or lungs
Insensitivity to ADH (nephrogenic diabetes insipidus)	
Lithium	
Tetracyclines	
Amphotericin B	
Acute tubular necrosis	

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus. If urine osmolality is high this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parenteral feeding) or excessive extrarenal loss of water (e.g. heat stroke).

Treatment

Treatment is that of the underlying cause, e.g.

- In ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH
- Remember to withdraw nephrotoxic drugs where possible and replace water either orally or, if necessary, intravenously.

In *severe* (>170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 h, as over-rapid correction may lead to cerebral oedema.

In *less severe* (e.g. >150 mmol/L) hypernatraemia, the treatment is 5% glucose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes – 5 L/day or more – may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see p. 646), this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 647.

DISORDERS OF POTASSIUM CONCENTRATION

Regulation of serum potassium concentration

The usual dietary intake varies between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the

Disorders of potassium concentration

body's potassium (3500 mmol in an adult man) is intracellular. Serum potassium levels are controlled by:

- uptake of K^+ into cells
- renal excretion
- extrarenal losses (e.g. gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na^+/K^+ -ATPase in the cell membrane and by H^+ concentration.

Uptake is **stimulated** by:

- insulin
- β -adrenergic stimulation
- theophyllines.

Uptake is **decreased** by:

- α -adrenergic stimulation
- acidosis – K^+ exchanged for H^+ across cell membrane
- cell damage or cell death – resulting in massive K^+ release.

Kidney plays the pivotal role in the maintenance of potassium balance by varying its secretion with changes in dietary intake. Over 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle and only <10% of the filtered load is delivered to the early distal tubule. Potassium absorption on proximal tubule is entirely passive and follows that of sodium and water, while its reabsorption in the thick ascending limb of the loop of Henle is mediated by the sodium-potassium-2-chloride cotransporter. However, potassium is secreted by the principal cells in the cortical and outer medullary collecting tubule. Secretion in these segments is very tightly regulated in health and can be varied according to individuals needs and is responsible for most of urinary potassium excretion.

Renal excretion of potassium is increased by aldosterone, which stimulates K^+ and H^+ secretion in exchange for Na^+ in the principal cells of the collecting duct (Fig. 13.8). Because H^+ and K^+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K^+ . Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K^+ homeostasis by affecting aldosterone release (e.g. heparin, NSAIDs) or by directly affecting renal potassium handling (e.g. diuretics).

Recent evidence has shown that other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. CD63, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A and C mediated phosphorylation inhibits conductance K channels in the principal cells of the collecting duct but the cytochrome p450-epoxygenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5–10 mmol/L of K^+ , but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium

Figure 13.8 Aldosterone-regulated transport in the cortical collecting ducts. Under normal conditions, the epithelial sodium channel is the rate-limiting barrier for the normal entry of sodium from the lumen into the cell. The resulting lumen-negative transepithelial voltage (indicated by the minus sign) drives potassium secretion from the principal cells and proton secretion from the α -intercalated cells (see Fig. 13.11). In **Liddle's syndrome**, a mutation in the gene encoding the epithelial sodium channel results in persistent unregulated reabsorption of sodium and increased secretion of potassium (not shown). In **pseudohypoaldosteronism type I** autosomal recessive, loss of function mutations (X) in this gene inactivate the channel. In the autosomal dominant variety, the mutation is in the gene encoding the mineralocorticoid regulation of the activity of the epithelial sodium channel. Either mechanism reduces the activity of the epithelial sodium channel, thus causing salt wasting and decreasing the secretion of potassium and protons.

is secreted by the colon, and diarrhoea contains 10–30 mmol/L of K^+ ; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and K^+ loss.

Hypokalaemia

Common causes

Causes

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. Acute hypokalaemia is often caused by intravenous fluids without potassium and redistribution into cells. The common causes are shown in Table 13.12.

Rare causes

These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter's syndrome (clinically similar to loop diuretics)

This consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see p. 657), normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (Fig. 13.6). Mutation in the genes encoding either the sodium-potassium-2-chloride cotransporter (NKCC2), the ATP-regulated renal outer medullary potassium channel (ROMK) or kidney-specific basolateral

Table 13.12 Causes of hypokalaemia

Increased renal excretion (urinary K^+ >20 mmol/day)	Reduced intake of K^+
Diuretics:	Intravenous fluids without K^+
Thiazides	Dietary deficiency
Loop diuretics	Redistribution into cells
Increased aldosterone secretion	β -Adrenergic stimulation
Liver failure	Acute myocardial infarction
Heart failure	Beta-agonists, e.g. fenoterol, salbutamol
Nephrotic syndrome	Insulin treatment, e.g. treatment of diabetic ketoacidosis
Cushing's syndrome	Correction of
Conn's syndrome	megaloblastic anaemia, e.g. B_{12} deficiency
ACTH-producing tumours	Alkalosis
Exogenous	Hypokalaemic periodic paralysis
mineralocorticoid	Gastrointestinal losses
Corticosteroids	(urinary K^+ <20 mmol/day)
Carbenoxolone	Vomiting
Liquorice (potentiates renal actions of cortisol)	Severe diarrhoea
Renal disease	Purgative abuse
Renal tubular acidosis	Villous adenoma
Types 1 and 2	Ileostomy or uterosigmoidostomy
Renal tubular damage (diuretic phase)	Fistulae
Acute leukaemia	Ileus/intestinal obstruction
Nephrotoxicity	
Amphotericin	
Aminoglycosides	
Cytotoxic drugs	
Release of urinary tract	
Obstruction	
Bartter's syndrome	
Liddle's syndrome	
Gitelman's syndrome	

chloride channels (ClC-Kb) – Bartter types I, II and III, respectively – causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. There is also an increased intrarenal production of prostaglandin E_2 which is secondary to sodium and volume depletion, hypokalaemia and the consequent neurohumoral response rather than a primary defect. PGE_2 causes vasodilatation and may explain why the blood pressure remains normal.

Barttin, a β -subunit for ClC-Ka and ClC-Kb chloride channels, is encoded by the BSND (Bartter's syndrome with sensorineural deafness) gene. Loss of function mutations cause type IV Bartter's syndrome associated with sensorineural deafness and renal failure. Barttin co-localizes with a subunit of the chloride channel in basolateral membranes of the renal tubule and inner ear epithelium. It appears to mediate chloride exit in the thick ascending limb (TAL) of the loop of Henle and chloride recycling in potassium-secreting strial marginal cells in the inner ear. A very rare variant of type IV is a disorder with an impairment of both chloride channels (ClC-Ka and ClC-Kb) producing the same phenotypic defects.

A gain of function mutation of the calcium sensing receptor (CaSR) which leads to autosomal dominant hypocalcaemia has also been recognized in Bartter's syndrome. In the kidney, the CaSR is expressed mainly in the basolateral membrane of cortical TAL. Activation of CaSR by high calcium or magnesium or by gain of function mutation triggers intracellular signalling, including release of arachidonic acid and inhibition of adenylate cyclase. Both actions result in inhibition of ROMK activity, which in turn leads to reduction in the lumen-positive electrical potential and transcellular absorption of calcium. This effect of CaSR explains why patients with mutations in this receptor may present with

both hypocalcaemia, hypercalciuria and renal wasting of NaCl, resulting in a Bartter-like syndrome.

In summary, these defects in sodium chloride transport are thought to initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic. The initial salt loss leads to mild volume depletion, resulting in activation of the renin-angiotensin-aldosterone system. The combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

Diagnostic pointers include high urinary potassium and chloride despite low serum values as well as increased plasma renin (NB: in primary aldosteronism, renin levels are low). Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (careful exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs.

Treatment is with combinations of potassium supplements, amiloride and indomethacin.

Gitelman's syndrome (similar to thiazide diuretics)

Gitelman's syndrome is a phenotype variant of Bartter's syndrome characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between the Gitelman's syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium-chloride cotransporter (NCCT) (Fig. 13.7). Analysis of the gene encoding the NCCT has identified loss of function mutations in Gitelman's syndrome.

Like Bartter's syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Unlike Bartter's syndrome, the degree of volume depletion and hypokalaemia is not sufficient to stimulate prostaglandin E_2 production. Impaired function of NCCT is predicted to cause hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium-calcium exchanger. The mechanism for urinary magnesium losses is described on page 656.

Treatment consists of potassium and magnesium supplementation ($MgCl_2$) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated. Elevated prostaglandin E_2 does not occur (see above) and, therefore, NSAIDs are not indicated in this disorder.

Liddle's syndrome

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This leads to constitutive activation of the epithelial sodium channel, resulting in excessive sodium reabsorption with

coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule results in volume expansion, inhibition of renin and aldosterone secretion and development of low renin hypertension (Fig. 13.8).

Therapy consists of sodium restriction along with amiloride or triamterene administration. Both are potassium-sparing diuretics which directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

Hypokalaemic periodic paralysis

This condition may be precipitated by carbohydrate intake, suggesting that insulin-mediated potassium influx into cells may be responsible. This syndrome also occurs in association with hyperthyroidism (thyrotoxic periodic paralysis) which occurs in Asians.

Clinical features

Hypokalaemia is usually asymptomatic, but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 648).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal, because adrenergic activation (for instance after myocardial infarction) causes both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action, and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease, but the pathogenesis is not completely understood.

Treatment

The underlying cause should be identified and treated where possible. Table 13.13 shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is required only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacidosis. When using intravenous therapy in the presence of poor

renal function, replacement rates <2 mmol per hour should be used only, with hourly monitoring of serum potassium and ECG changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use a glucose solution as this would make hypokalaemia worse.

The treatment of adrenal disorders is described on page 958.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

Hyperkalaemia

Causes

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (Table 13.14). The most common causes are renal impairment and drug interference with potassium excretion. The combination of ACE inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

Rare causes

Hyporeninaemic hypoaldosteronism

This is also known as type 4 renal tubular acidosis (see p. 664). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

Pseudohypoaldosteronism type 1 (autosomal recessive and dominant types)

This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalaemia.

Table 13.14 Causes of hyperkalaemia

Decreased excretion	Increased extraneous load
Acute kidney injury ^a	Potassium chloride
Drugs: ^a	Salt substitutes
Amiloride	Transfusion of stored blood ^a
Triamterene	
Spironolactone/eplerenone	Spurious
ACE inhibitors/ACE blockers ^a	Increased <i>in vitro</i> release from abnormal cells
NSAIDs	Leukaemia
Ciclosporin treatment	Infectious
Heparin treatment	mononucleosis
Aldosterone deficiency	Thrombocytosis
Hyporeninaemic hypoaldosteronism (RTA type 4)	Familial
Addison's disease	pseudohyperkalaemia, e.g. haemolysis in syringe
Acidosis ^a	Increased release from muscles
Gordon's syndrome	Vigorous fist clenching during phlebotomy
Increased release from cells	
(decreased Na ⁺ /K ⁺ -ATPase activity)	
Acidosis	
Diabetic ketoacidosis	
Rhabdomyolysis/tissue damage	
Tumour lysis	
Succinylcholine (amplified by muscle denervation)	
Digoxin poisoning	
Vigorous exercise	
(α -adrenergic; transient)	

^aCommon causes.

Table 13.13 Treatment of hypokalaemia

Cause	Treatment
Dietary deficiency	Increase intake of fresh fruit/vegetables or oral potassium supplements (20–40 mmol daily). (Potassium supplements can cause gastrointestinal irritation)
Hyperaldosteronism , e.g. cirrhosis, thiazide therapy	Spironolactone/eplerenone. Co-prescription of a potassium-sparing diuretic with a similar onset and duration of action
Intravenous fluid replacement	Add 20 mmol of K ⁺ /L of fluid with monitoring

mia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium channel activity (opposite to Liddle's syndrome). This disorder involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal dominant type is due to mutations affecting the mineralocorticoid receptor (Fig. 13.8). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

Hyperkalaemic periodic paralysis (see p. 1153)

This is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium channel gene.

Gordon's syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)

This appears to be a mirror image of Gitelman's syndrome (see p. 653), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium-chloride cotransporter (NCCT) is involved. Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and further genetic heterogeneity has also been found. These genes do not correspond to ionic transporters but to unexpected proteins, WNK (With No lysine Kinase) 1 and WNK 4, which are two closely related members of a novel serine-threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss of function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity as seen from the patient's phenotype. WNK 1 is an inhibitor of WNK 4 and in some patients with Gordon's syndrome, gain of function mutation in WNK 1 results in functional deficiency of WNK 4 and overactivity of NCCT.

Suxamethonium and other depolarizing muscle relaxants

These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features

Serum potassium of >7.0 mmol/L is a medical emergency and is associated with ECG changes. Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia and eventual asystole.

Treatment

Treatment for severe hyperkalaemia requires both urgent measures to save lives and maintenance therapy to

Emergency Box 13.1

Correction of severe hyperkalaemia

Immediate

ECG monitor and i.v. access

Protect myocardium

10 mL of 10% calcium gluconate i.v. over 5 min
Effect is temporary but dose can be repeated after 15 min

Drive K^+ into cells

Insulin 10 units + 50 mL of 50% glucose i.v. over 10–15 min followed by regular checks of blood glucose and plasma K^+

Repeat as necessary:

- and/or correction of severe acidosis ($pH < 6.9$) – infuse $NaHCO_3$ (1.26%)
- and/or salbutamol 0.5 mg in 100 mL of 5% glucose over 15 min (rarely used)

Later

Deplete body K^+ (to decrease plasma K^+ over the next 24 hours)

Polystyrene sulphonate resins:

15 g orally up to three times daily with laxatives
30 g rectally followed 9 h later by an enema

Haemodialysis or peritoneal dialysis if the above fails.

keep potassium down, as summarized in Emergency Box 13.1. The cause of the hyperkalaemia should be found and treated.

High potassium levels are cardiotoxic as they inactivate sodium channels. Divalent cations, e.g. calcium, restore the voltage dependability of the channels. Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological insulin (20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 min, but must be accompanied by glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 h after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended.

Intravenous or nebulized salbutamol (10–20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremors at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion and should not be used; 1.26% is used with severe acidosis ($pH < 6.9$). Gastric aspiration will remove potassium and leads to alkalosis.

Ion-exchange resins (polystyrene sulphonate resins) are used as maintenance therapy to keep potassium down after emergency treatment. They make use of the ion fluxes which occur in the gut to remove potassium from the body, and are the only way short of dialysis of removing potassium from the body. They may cause fluid overload (resonium contains Na^+) or hypercalcaemia (calcium resonium). Resins do not appear to significantly enhance the excretion of potassium beyond the effect of diarrhoea induced by osmotic or secretory cathartics.

In general, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange

a Normal

b Tented T wave (arrow)

c Reduced P wave (arrow) with widened QRS complex

d 'Sine wave' pattern (pre-cardiac arrest)

Progressive ECG changes with increasing hyperkalaemia.

removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in renal failure.

DISORDERS OF MAGNESIUM CONCENTRATION

Magnesium (Mg²⁺) plays a pivotal role in many biological processes such as enzymatic reactions, gene transcription, bone remodelling, and neuromuscular stability. Approximately 99% of the Mg²⁺ in the body is in the intracellular compartment, mainly in bone (~85%) and muscle and soft tissues (~14%). The other 1% is in the extracellular fluid.

Plasma magnesium levels are normally maintained within the range 0.7–1.1 mmol/L (1.4–2.2 mEq/L). The average daily magnesium intake is 15 mmol, which is absorbed mainly in the small intestine and to a lesser extent in the colon. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed. The kidney reabsorbs between approximately 95% and 98% of the filtered Mg²⁺ and plays a major role in maintaining plasma Mg²⁺ concentrations within the normal range.

Renal handling of magnesium

Cortical thick ascending limb of Henle (cTAL)

Approximately 30% of Mg²⁺ is bound to plasma proteins but the remaining fraction is freely filterable. The major site of magnesium transport is the cortical thick ascending limb (cTAL) of the loop of Henle, where 65–70% of the filtered load is reabsorbed with only 10–20% being reabsorbed in the proximal tubule (Fig. 13.6). This transport is passive, paracellular and carried out by tight junction proteins (paracellin-1 and claudins). This process is driven by the lumen-positive electrochemical gradient, characteristic of this segment. This voltage gradient is created by the apical disproportionate net transport of two Cl[−] to one Na⁺ (by the bumetanide-sensitive sodium-potassium-2-chloride transporter) and the secretion of K⁺ (via the ROMK) (see Fig. 13.6). Loss of function mutations in these key reabsorptive processes lead to hypomagnesaemia as part of distinctive clinical syndromes described below.

Bartter's syndrome (p. 652). Hypomagnesaemia is not present in all patients with Bartter's syndrome because expected dissipation of the luminal positive voltage gradient is prevented by lack of dilution of tubular fluid which maintains transepithelial voltage in the normal range. Compensatory increased absorption of Mg²⁺ in the distal convoluted tubule (DCT) can also partly prevent hypomagnesaemia in this condition.

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis (FHHNC) is characterized by excessive renal magnesium and calcium wasting. Individuals develop bilateral nephrocalcinosis and progressive chronic kidney disease. Patients also have elevated PTH levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extrarenal involvement such as myopia, nystagmus, chorioretinitis has been reported. The main defect in magnesium and calcium reabsorption lies in cTAL. Ten different mutations have been identified in a novel gene which encodes for paracellin-1 and claudins 16/19 complex, members of the claudin family of tight junction proteins (see p. 23).

Distal convoluted tubule (DCT)

The reabsorption rate in the DCT (10%) is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct: 3–5% of filtered magnesium is finally excreted in the urine. Magnesium reabsorption in the DCT is transcellular and active (Fig. 13.7). The DCT has a slight lumen-negative voltage of approximately −5 mV. The luminal Mg²⁺ concentration in the DCT ranges between 0.2 and 0.7 mmol/L, whereas the intracellular concentration of Mg²⁺ is estimated to be maintained around 0.2–1.0 mmol/L. Therefore the voltage difference across the apical membrane plays a key role in Mg²⁺ transport within the DCT. Magnesiotropic proteins, including the transient receptor potential channel melastatin member 6 (TRPM6), the pro-epidermal growth factor (EGF), the potassium channels Kir4.1 as well as the hepatocyte nuclear factor 1B (HNF1B) are situated in DCT.

TRPM6 is a member of the transient receptor potential channel family. It is an Mg²⁺-permeable channel that is also expressed in the luminal membrane of the intestinal epithelium. Inactivating mutations of TRPM6, a rare autosomal recessive disease, thus cause a combination of impaired gut absorption of Mg²⁺ and renal wasting known as **hypomagnesaemia with secondary hypocalcaemia (HSH)**. It is characterized by disturbed neuromuscular excitability, muscle spasms, tetany and generalized convulsions. Severe hypomagnesaemia is observed (0.1–0.4 mmol/L) due to impaired intestinal Mg²⁺ absorption and renal reabsorption.

The epidermal growth factor (EGF) resides on the basolateral surface of the DCT cells. It markedly stimulates the activity of TRPM6. Loss of function mutation results in an autosomal recessive form of **isolated renal hypomagnesaemia (IRH)**. IRH presents with hypomagnesaemia (0.53–0.66 mmol/L) and an inappropriately high fractional excretion of Mg²⁺ with epileptic seizures and moderate mental retardation. In contrast to HSH, Ca²⁺ handling is not affected in these patients. Cancer therapies which inhibit EGF also cause hypomagnesaemia by the above mechanism.

Thiazide-sensitive Na⁺-Cl[−] cotransporter in the DCT plays a role in sodium and chloride absorption and maintenance of lumen-negative voltage. Loss of function mutation in this cotransporter results in *Gitelman's syndrome* (p. 645; see Fig. 13.7). Hypomagnesaemia is likely due to a reduced abundance of TRPM6. The observed hypocalciuria is caused by an increased proximal tubular reabsorption, a process that occurs in response to the mild volume depletion.

The γ-subunit of the Na⁺-K⁺-ATPase on the basolateral aspect of DCT plays a pivotal role in the sodium and chloride absorption and maintenance of lumen-negative voltage (a key requirement for magnesium absorption) in this segment of the nephron. A loss of function mutation in the FXD2 gene (transcription factor for gamma chain of Na⁺-K⁺-ATPase) causes **isolated dominant hypomagnesaemia**. The affected individuals present with renal Mg²⁺ wasting, accompanied by hypocalciuria.

The HNF1b gene encodes a transcription factor linked to the regulation of the FXD2 gene. Defects in HNF1b gene have been implicated in genetic defects of beta-cell function (p. 1007). Interestingly, almost half of the carriers of a mutation in the HNF1b gene display hypomagnesaemia (<0.65 mmol/L) due to renal wasting of Mg²⁺. As in patients with FXD2 mutations, hypocalciuria is present.

ATP-sensitive inward rectifier potassium channel 10 (Kir4.1) is present on the basolateral surface of DCT. It allows K⁺ ions to recycle across the basolateral membrane, thereby maintaining an adequate supply of K⁺ to sustain the high

$\text{Na}^+\text{-K}^+\text{-ATPase}$ activity observed in this segment. Loss of its function has been linked to a new hypomagnesaemic syndrome, EAST syndrome. The impaired electrogenic $\text{Na}^+\text{-K}^+\text{-ATPase}$ transport causes depolarization of the apical membrane and reduces inward transport of Mg^{2+} via TRPM6. Patients have epilepsy, ataxia, sensorineural deafness (Kir 4.1 is present in the inner ear), and tubulopathy (of a Gitelman-like phenotype).

Hypomagnesaemia

In addition to the familial causes above, hypomagnesaemia most often develops as a result of deficient intake, defective gut absorption, or excessive gut or urinary loss (Table 13.15). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis. The serum magnesium is usually <0.7 mmol/L (1.4 mEq/L). The phenotypes can in many cases be mimicked by drug treatment such as aminoglycosides and cisplatin compounds. Due to the severe effects of hypomagnesaemia, routine measurements of serum Mg^{2+} should be conducted in the critically ill as well as in patients who are exposed to drugs and other conditions associated with Mg^{2+} deficiency.

Clinical features

Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyperreflexia, confusional and hallucinatory states and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves, and occasional shortening of the ST segment.

Treatment

This involves the withdrawal of precipitating agents such as diuretics or purgatives. If symptomatic (or with hypocalcaemia), give a parenteral infusion of 50 mmol of magnesium

chloride in 1 L of 5% glucose or other isotonic fluid over 12–24 h. This should be repeated daily and continued for 2 days after normal plasma levels have been achieved.

Relationship between hypomagnesaemia and plasma calcium

Calcium deficiency usually but not always develops with hypomagnesaemia. Hypomagnesaemia can be further subdivided into three main groups:

- **Hypercalciuria** with hypomagnesaemia: this originating from defects in Mg^{2+} absorption in cTAL such as several forms of Bartter's syndrome, loop diuretics and familial hypomagnesaemia with hypercalciuria and nephrocalcinosis (FHHNC).
- **Normocalciuria**: this includes autosomal dominant hypomagnesaemia due to mutations in Kv1.1, isolated renal hypomagnesaemia (IRH) due to mutations in the EGF gene.
- **Hypocalciuria with hypomagnesaemia**: is a hallmark feature of thiazide diuretic use, Gitelman's syndrome (GS), and has also been reported in the EAST syndrome, due to mutations in NCC and Kir4.1, respectively. Genetic defects of beta-cell function and isolated dominant hypomagnesaemia (IDH) caused by mutations in HNF1b and FXYD2 also lead to hypomagnesaemia with accompanying hypocalciuria.

Relationship between hypomagnesaemia and plasma potassium

Magnesium depletion can lead to refractory hypokalaemia. The intracellular magnesium blocks secretory K^+ currents through ROMK channels; therefore, magnesium depletion promotes K^+ loss. Furthermore, this magnesium-mediated inhibition of K^+ secretion increases as extracellular K^+ decreases, which appropriately reduces K^+ loss in the presence of K^+ deficiency. Close monitoring, with potassium supplements if necessary, is required in patients presenting with primary symptomatic low plasma magnesium levels.

Hypermagnesaemia

This primarily occurs in patients with acute or chronic kidney disease given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Table 13.16.

Clinical features

Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

Treatment

Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with glucose and insulin (as for hyperkalaemia) to lower the plasma magnesium level. Dialysis may be required in patients with severe kidney disease.

Table 13.15 Causes of hypomagnesaemia

Decreased magnesium absorption	Gut losses
Malabsorption (severe)	Prolonged nasogastric suction
Malnutrition	Excessive purgation
Alcohol excess	Gastrointestinal/biliary fistulae
Hypomagnesaemia with secondary	Severe diarrhoea
Hypocalcaemia (p. 996)	Inherited tubular wasting
Increased renal excretion	Bartter's syndrome
Drugs:	Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis
Loop diuretics	Isolated dominant hypomagnesaemia
Thiazide diuretics	Gitelman's syndrome (p. 645)
Digoxin	Isolated recessive hypomagnesaemia
Proton pump inhibitors	Hypomagnesaemia with secondary hypocalcaemia (HSH)
Diabetic ketoacidosis	East syndrome
Hyperaldosteronism	Miscellaneous
SIADH	Acute pancreatitis
Alcohol excess	
Hypercalciuria	
1,25-(OH)-vitamin D ₃ deficiency	
Drug toxicity:	
Amphotericin	
Aminoglycosides	
Cisplatin	
Ciclosporin	

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

DISORDERS OF PHOSPHATE CONCENTRATION

Phosphate forms an essential part of most biochemical systems, from nucleic acids downwards. The regulation of plasma phosphate level is both direct and closely linked to calcium.

About 85% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.15 mmol/L (2.5–3.6 mg/dL) and accounts for only 1% of the total body phosphate. However, plasma phosphate levels correlate in most circumstances with total body sodium. Phosphate reabsorption from the glomerular filtrate occurs entirely and actively in the renal proximal tubule and is hormonally regulated. It is decreased by parathyroid hormone (PTH), mediated by a cyclic AMP-dependent mechanism; thus hyperparathyroidism is associated with low plasma levels of phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D_3 , sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity.

Osteoblast-secreted phosphaturic factors (phosphatonins) such as fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4) play a role in phosphate homeostasis. FGF23 is the most extensively investigated phosphatonin which binds to its receptors FGFR1 in the kidney and causes phosphaturia and also regulates vitamin D by inactivation of 1α -hydroxylase (CYP27B1) and upregulation of 24 hydroxylase (CYP24A1) enzymes with the net result of low 1,25 vitamin D synthesis. Moreover, FGF23 requires *Klotho* (p. 652) to act as a coreceptor with FGFR1 for its activity. Loss of function mutation in either FGF23 or *Klotho* results in a similar phenotype of shortened lifespan, premature ageing (p. 37) including hyperphosphataemia and as expected from mode of action increased 1–25 vitamin D levels. *Klotho* can also inhibit phosphate absorption directly in the absence of FGF23 or PTH.

Phosphate absorption is an active process carried out by a family of sodium-phosphate cotransporters (NPT) in the gut and kidneys. NPT2a and NPT2c are expressed in the brush border of the renal proximal tubule whilst NPT2b is expressed in lungs and intestine. NPT2a plays a central role in the renal reabsorption of phosphate but essentially requires a companion protein called sodium hydrogen exchanger regulatory factor 1 (NHERF1) for membrane sorting. Intestinal absorption is carried out by NPT2b but its mutation does not cause any phosphate abnormalities because of the compensation taking place by the renal expression of NPT2a and possibly NPT2c. Under normal circumstances plasma phosphate levels are kept constant, e.g. after a phosphate-rich meal, the intestinal bone axis releases FGF23 from bone which inhibits

Table 13.17 Causes of hypophosphataemia

Redistribution	Renal losses
Respiratory alkalosis	Hyperparathyroidism
Treatment of diabetic ketoacidosis (insulin drives phosphate into cells)	Renal tubular defects
Refeeding (particularly with carbohydrate) after fasting or starvation	Diuretics
After parathyroidectomy (hungry bone disease)	Hypophosphataemic rickets
Decreased intake/absorption	Vitamin D-dependent rickets, types I and II
Dietary	Tumour induced
Malabsorption	Autosomal dominant and recessive
Vomiting	X-linked dominant
Gut phosphate binders, e.g. sevelamer	Dent's disease
Vitamin D deficiency	
Alcohol withdrawal	

NPT2a and causes phosphate excretion. Moreover, phosphate in the plasma either directly or indirectly by lowering ionized calcium causes the release of PTH which also inhibits NPT2a and NHERF1 resulting in phosphaturia (Fig. 13.9). These two principal mechanisms keep plasma phosphate levels within normal limits on a daily basis.

Hypophosphataemia

Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, to renal losses, or to decreased intake (Table 13.17).

Clinical features include:

- Muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- A left shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate, 2,3-BPG) and rarely haemolysis
- Confusion, hallucinations and convulsions.

Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede weaning a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

Causes

Primary hyperparathyroidism is a common cause of hypophosphataemia. Very rarely, gain of function mutations of PTH1 receptor cause hypophosphataemia and Jansen's metaphyseal chondrodysplasia due to constitutive activation of PTH signaling even in the presence of low or absent circulating PTH levels.

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency either dietary (globally the commonest cause) or genetic and is usually accompanied by hypocalcaemia (calcipenic) and secondary hyperparathyroidism.

Vitamin D-dependent rickets type I

Also known as *pseudovitamin D-deficient rickets*, this is caused by 1α -hydroxylase deficiency due to inactivating mutations in its gene. It can be corrected with high daily doses of vitamin D. This condition manifests clinically in

the first year of life with severe hypocalcaemia often complicated by tetany, moderate hypophosphataemia and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25-hydroxyvitamin D and low values of 1,25-dihydroxyvitamin D and usually relatively high PTH levels. The treatment of choice is replacement therapy with calcitriol.

Vitamin D-dependent rickets type II

This is a form of vitamin D resistance and is now known as **hereditary vitamin D-resistant rickets**. It is an autosomal recessive disorder and is usually caused by loss of function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending upon the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life with alopecia in two-thirds of cases which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves a therapeutic trial of calcitriol and calcium supplementation. Long-term infusion of calcium into a central vein is a possible alternative for severely resistant patients. Oral calcium therapy may be sufficient once radiographic healing has been observed.

Decreased renal reabsorption of phosphate Excessive phosphatonins (FGF23)

This condition also occurs in patients with *tumour-induced osteomalacia* (TIO), *X-linked dominant hypophosphataemic rickets* (XLR), and *autosomal-dominant hypophosphataemic rickets* (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophosphataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations, and normal or low 1,25-dihydroxyvitamin D₃. Urinary cyclic AMP levels are generally in the normal range.

In **TIO**, there is excessive production of phosphaturic agents (which are normally produced by osteoblasts and act as hormones by acting on kidneys and regulating phosphate absorption and vitamin D activation), e.g. fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4). These cannot be degraded by normal concentrations of PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome). This results in net excess of inhibitors of the sodium-phosphate cotransporter in the proximal tubule, and phosphaturia.

In **ADHR**, FGF-23 is mutated so that it is resistant to PHEX proteolysis. In XLR, mutations in PHEX prevent binding to FGF23 and FRP-4, resulting in a net relative excess of phosphatonins.

Normal adaptive increases in 1,25-dihydroxyvitamin D₃ synthesis in response to low phosphate levels do not occur in TIO, ADHR and XLR, aggravating phosphaturia (Fig. 13.9).

Autosomal recessive hypophosphataemia with high FGF23 levels has been described in patients with mutations in the gene encoding dentin matrix protein 1 (DMP1), which is a transcription factor produced by dental cells, osteoblasts and osteocytes. It is also secreted and can modulate the formation of mineralized matrix.

Reduced NPT2a/NHERF1 activity

Mutations in NPT2a (sodium phosphate cotransporter 2a) and NHERF1 (sodium hydrogen regulator factor 1) have been

identified in patients with low phosphate levels and reduced ratio of the maximum tubular reabsorption of phosphate (TmP) normalised for GFR (TmP/GFR ratio). Heterozygous loss of function mutation in NPT2a and NHERF1 in patients is characterized by hypophosphataemia, low TmP/GFR and normal PTH. Carriers of these mutations do not have hypercalcaemia, which means these mutation do not affect the action of PTH on bones.

Dent's disease

Dent's disease is the generally accepted name for a group of hereditary tubular disorders including X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphataemic rickets, and idiopathic low-molecular-weight proteinuria. It is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones and eventual renal failure, with some patients developing rickets or osteomalacia.

Dent's disease is caused by loss of function mutation of a proximal tubular endosomal chloride channel, CIC5. This chloride channel, along with the proton pump, is essential for acidification of proximal tubular endosomes. The process is linked with normal endocytosis, degradation and recycling of absorbed proteins, vitamins and hormones. Defective endosomal acidification (owing to the mutated CIC5 gene) results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH with clinical phenotype of hyperparathyroidism. Moreover, the receptors (megalin and cubilin) for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules are decreased in Dent's disease. This explains low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

Diagnostic approach

Patients with hypophosphataemia should have their TmP/GFR measured. A value of <0.7 mmol/L indicates renal phosphate wasting. If PTH levels are high then it is very likely to be hyperparathyroidism either primary or secondary to vitamin D deficiency (acquired or genetic) or Dent's disease. If PTH levels are low then the only possibility is gain of function mutation in PTH1R. If PTH levels are normal then assess FGF23 levels. High FGF23 levels will indicate possible mutated genes in FGF23/Klotho, PHEX and DMP1. Normal FGF23 and PTH levels point to mutations in NPT2a, NPT2c and NHERF1.

Treatment

Treatment for hypophosphataemia includes combined therapy with phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration.

Treatment of acute hypophosphataemia, if warranted, is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours, with repeated measurements of calcium and phosphate, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. *Chronic hypophosphataemia* can be corrected, if warranted, with oral effervescent sodium phosphate.

Hyperphosphataemia

Hyperphosphataemia is common in patients with CKD (see p. 618 and Table 13.18). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium or of alkalosis. Uraemic itching may be caused by a

raised calcium phosphate product. Prolonged hyperphosphataemia causes hyperparathyroidism, and periarticular and vascular calcification.

Familial tumoral calcinosis is characterized by calcifications of muscles, skin, eyelids and vessels as well hyperostosis. Absence of glycosylation of FG23 makes it unstable and more sensitive to proteolysis. This results in its deficiency and hyperphosphataemia due to increased renal phosphate reabsorption through increased NPT2a activity.

Usually, no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 622).

Table 13.19 Relationship between $[H^+]$ and pH

pH	[H ⁺] (nmol/L)
6.9	126
7.0	100
7.1	79
7.2	63
7.3	50
7.4	40
7.5	32
7.6	25

blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration $[H^+]$ because blood pH is the negative logarithm of $[H^+]$ (Table 13.19). The $[H^+]$ at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the $[H^+]$ – a fall in pH – is termed acidemia. A decrease in $[H^+]$ – a rise in the blood pH – is termed alkalemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

ACID-BASE DISORDERS

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. The

Normal acid–base physiology

The normal adult diet contains 70–100 mmol of acid. Throughout the body, there are buffers that minimize any changes in blood pH that these ingested hydrogen ions

might cause. Such buffers include intracellular proteins (e.g. haemoglobin) and tissue components (e.g. the calcium carbonate and calcium phosphate in bone) as well as the bicarbonate-carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions [HCO_3^-] and carbonic acid (H_2CO_3) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following equation:

The addition of hydrogen ions drives the reaction to the right, decreasing the plasma bicarbonate concentration [HCO_3^-] and increasing the arterial carbon dioxide pressure ($P_a\text{CO}_2$). As shown in the following Henderson–Hasselbalch equation, a fall in the plasma [HCO_3^-] increases [H^+] and thus lowers blood pH:

$$[\text{H}^+] = 181 \times P_a\text{CO}_2 [\text{HCO}_3^-]$$

where [H^+] is expressed in nmol/L, $P_a\text{CO}_2$ in kilopascals, [HCO_3^-] in mmol/L and 181 is the dissociation coefficient of carbonic acid. Alternatively the equation can be expressed as:

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]$$

where $\text{pK} = 6.1$. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO_3^-] to normal. Maintenance of a normal plasma [HCO_3^-] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Renal reabsorption of bicarbonate

The plasma [HCO_3^-] is normally maintained at approximately 25 mmol/L. In individuals with a normal glomerular filtration rate (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO_3^-] would fall, along with blood pH. Thus, maintenance of normal plasma [HCO_3^-] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 13.10).

The proximal convoluted tubule reclaims 85–90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal (brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalysed by the Na^+/K^+ -ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are

Figure 13.10 Resorption of sodium bicarbonate in the renal (mainly proximal) tubule. Bicarbonate is reclaimed by the secretion of H^+ in exchange for Na^+ into the tubule. This results in the formation of H_2CO_3 , which is then broken down to CO_2 . This is reabsorbed and converted back to H_2CO_3 , which now dissociates into H^+ and HCO_3^- . The net result is reabsorption of Na^+ and HCO_3^- . This process is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.

transported in the opposite direction (at the Na^+/H^+ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV) carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of [H^+] (Fig. 13.11)

More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than into any other nephron segment. However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H_2SO_4), which then reacts with sodium bicarbonate as follows:

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO_3^-]. This fall in plasma [HCO_3^-] leads to a slight decrease in the blood pH, although a smaller decrease in the blood pH than would have occurred if buffer were

Figure 13.11 Renal excretion of H⁺. Secretion of H⁺ from the cortical collecting ducts is indirectly linked to Na⁺ reabsorption. Intracellular potassium is exchanged for sodium in the principal cell. Aldosterone stimulates H⁺ secretion by entering the principal cell, where it opens Na⁺ channels in the luminal membrane and increases Na⁺/K⁺-ATPase activity. The movement of cationic Na⁺ into the principal cells then creates a negative charge within the tubule lumen. K⁺ moves from the electrochemical gradient and into the lumen. Aldosterone apparently also stimulates the H⁺-ATPase directly in the intercalated cell, further enhancing H⁺ secretion. When the urinary pH falls to 4.0–4.5, further H⁺ secretion by the α -intercalated cells ceases. The filtration of titratable acids (e.g. phosphoric acid, H₂PO₄) raises the intraluminal pH and permits this process to continue. Secreted H⁺ binds to the conjugate anion of a titratable acid (HPO₄²⁻ in this case) and is excreted in the urine. The H⁺ to be secreted arises from the reassociation of H₂O and CO₂ in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H⁺ is eliminated in the urine.

unavailable. The subsequent excretion of hydrogen ions takes place primarily in the collecting duct and results in the regeneration of 1 mmol of bicarbonate for every mmol of hydrogen ions excreted in the urine.

The *collecting duct* has three types of cells:

- The **principal cell** with an aldosterone-sensitive Na⁺ absorption site. These cells reabsorb Na⁺ and H₂O and secrete K⁺ under the influence of aldosterone.
- The **α -intercalated cell**, which possesses the proton pump for the active secretion of hydrogen ions in exchange for reabsorption of K⁺ ions. Aldosterone increases H⁺ ion secretion.
- The **β -intercalated cells** are mirror images of α -intercalated cells where the H⁺-ATPase pump is located in the basolateral rather than the apical membrane whereby H⁺ ions are secreted into the peritubular capillary. The HCO₃⁻ ions, on the other hand, are secreted into the tubular lumen by an anion exchanger in the apical membrane. The identity of this transporter is uncertain, however, as it does not appear to represent the same Cl⁻-HCO₃⁻ exchanger that is present in the basolateral membrane of the H⁺-secreting intercalated cells.

Secretion of hydrogen ions from the cortical collecting duct is indirectly linked to sodium reabsorption. Aldosterone

has several facilitating effects on hydrogen ion secretion. Aldosterone opens sodium channels in the luminal membrane of the principal cell and increases Na⁺/K⁺-ATPase activity. The subsequent movement of cationic sodium into the principal cell creates a negative charge within the tubule lumen. Potassium ions from the principal cells and hydrogen ions from the α -intercalated cells move out from the cells down the electrochemical gradient and into the lumen. Aldosterone also stimulates directly the H⁺-ATPase in the α -intercalated cell, further enhancing hydrogen ion secretion.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction of these excess hydrogen ions remains in solution. Here, they increase the urinary [H⁺] and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps such as H⁺-ATPase severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

In the presence of alkali excess, the homeostatic needs are reversed. Although the kidney can excrete excess alkaline load by reducing reabsorption of filtered bicarbonate in the proximal and distal tubule, the collecting ducts also contribute by secreting bicarbonate brought about by switching to β -intercalated cells. This switch enables kidneys to secrete bicarbonate and conserve H⁺ ions.

Buffer systems in acid excretion

Two buffer systems are involved in acid excretion: the titratable acids such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50–100 mmol under physiological conditions (Fig. 13.11).

Titratable acid

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK_a 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (Fig. 13.11).

Ammonium (NH₄⁺)

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 13.12).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalysed by glutaminase, resulting in α -ketoglutaric acid (Fig. 13.12) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of Henle's loop. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. The notion that ammonia diffuses down its concentration gradient into the lumen of the collecting tubule

Figure 13.12 The ammonia buffering system in the kidney. All ammonia used to buffer H^+ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, α -ketoglutarate (α -KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an $Na^+-HCO_3^-$ cotransporter.

has recently been challenged by the discovery of rhesus (Rh) associated glycoproteins acting as ammonia transport proteins also called RhCG/Rhcg which are expressed in the basolateral and apical surfaces of DCT, inner medullary collecting duct and type A intercalated cells. These proteins play a fundamental role in renal ammonia excretion under both basal and acidosis states. Once secreted, NH_3 reacts with the hydrogen ions secreted by the collecting tubular cells to form ammonium. Because ammonium (NH_4^+) is not lipid-soluble, it is trapped in the lumen and excreted in the urine as ammonium chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.

Glutamine metabolism and ureagenesis in the liver were thought to play a role in acid-base homeostasis. The liver was believed to contribute to regulation of acid-base balance by controlling the rate of ureagenesis and therefore bicarbonate consumption in response to changes in plasma acidity. Studies in human volunteers have concluded that ureagenesis is a maladaptive process for acid-base regulation and that ureagenesis has no discernible homeostatic effect on acid-base equilibrium in humans.

Causes of acid-base disturbance

Acid-base disturbance may be caused by:

- Abnormal CO_2 removal in the lungs ('respiratory' acidosis and alkalosis)
- Abnormalities in the regulation of bicarbonate and other buffers in the blood ('metabolic' acidosis and alkalosis).

Both may, and usually do, co-exist. For instance, metabolic acidosis causes hyperventilation (via medullary chemoreceptors, see p. 794), leading to increased removal of CO_2 in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention, which could be mistaken for primary metabolic alkalosis. The situation is even more complex if

Figure 13.13 The Flenley acid-base nomogram. This was derived from a large number of observations in patients with 'pure' respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid-base disturbance. The central white box shows the approximate limits of arterial pH and PCO_2 in normal individuals.

Table 13.20 Changes in arterial blood gases

	pH	P_aCO_2	HCO_3^-
Respiratory acidosis	N or ↓	↑↑	↑ (compensated)
Respiratory alkalosis	N or ↑	↓↓	↓ (slight)
Metabolic acidosis	N or ↓	↓	↓↓
Metabolic alkalosis	N or ↑	↑ (slight)	↑↑

a patient has both respiratory disease and a metabolic disturbance.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Table 13.20 shows the typical blood changes, but in complicated patients the acid-base nomogram (Fig. 13.13) is invaluable. The $[H^+]$ and P_aCO_2 are measured in arterial blood (for precautions see p. 659) as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the $[H^+]$ is high (pH low) but the P_aCO_2 is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO_2 elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO_2 removal (this is the most common 'combined' abnormality in practice).

Respiratory acidosis and alkalosis

Respiratory acidosis

This is caused by retention of CO_2 . The P_aCO_2 and $[H^+]$ rise. Renal retention of bicarbonate may partly compensate, returning the $[H^+]$ towards normal (see p. 876).

FURTHER READING

Weiner ID, Verlander JW. Molecular physiology of the Rh ammonia transport proteins. *Curr Opin Nephrol Hypertens* 2010; 19(5):471-477.

Respiratory alkalosis

Increased removal of CO_2 is caused by hyperventilation, so there is a fall in P_aCO_2 and $[\text{H}^+]$ (see p. 876).

Metabolic acidosis

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma $[\text{HCO}_3^-]$. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g. lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. Calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

The anion gap

The first step is to identify whether the acidosis is due to retention of H^+Cl^- or to another acid. This is achieved by calculation of the anion gap.

- The normal cations present in plasma are Na^+ , K^+ , Ca^{2+} , Mg^{2+} .
- The normal anions present in plasma are Cl^- , HCO_3^- , negative charges present on albumin, phosphate, sulphate, lactate, and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma $[\text{Na}^+]$, $[\text{K}^+]$, $[\text{Cl}^-]$ and $[\text{HCO}_3^-]$ is usually easily available.

$$\text{ANION GAP} = \{[\text{Na}^+] + [\text{K}^+]\} - \{[\text{HCO}_3^-] + [\text{Cl}^-]\}$$

Because there are more unmeasured anions than cations, the normal anion gap is 10–18 mmol/L, although calculations with more sensitive methods place this at 6–12 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 g/L to 20 g/L may reduce the anion gap by as much as 6 mmol/L, because each 1 g/L of albumin has a negative charge of 0.2–0.28 mmol/L.

Metabolic acidosis with a normal anion gap

If the anion gap is normal in the presence of acidosis, this suggests that H^+Cl^- is being retained or that $\text{Na}^+\text{HCO}_3^-$ is being lost. Causes of a normal-anion-gap acidosis are given in Table 13.21. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electro-

neutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidoses.

Renal tubular acidosis (RTA)

This term refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid–base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease.

Type 4 renal tubular acidosis

Also called 'hyporeninaemic hypoaldosteronism', this is probably the most common of these disorders. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild chronic kidney disease, usually caused by tubulo-Interstitial disease (e.g. reflux nephropathy) or diabetes. Gordon's syndrome (see p. 655) shares biochemical abnormalities but differs in having normal GFR and hypertension. Plasma renin and aldosterone are found to be low, even after measures which would normally stimulate their secretion. The features for the diagnosis are shown in Table 13.22. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics, or ion exchange resins to remove potassium, or a combination of these. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis (RTA)

This condition is vanishingly rare, and represents a combination of type 1 and type 2. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification, and mental retardation.

Type 2 ('proximal') renal tubular acidosis

This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na^+H^+ antiporter in the apical membrane and $\text{Na}^+\text{HCO}_3^-$ cotransporter in the basolateral membrane of proximal tubular cells respectively (see Fig. 13.10). Treatment is with sodium bicarbonate: massive doses may be required to overcome the renal 'leak'.

Table 13.21 Causes of metabolic acidosis with a normal anion gap

Increased gastrointestinal bicarbonate loss	Decreased renal hydrogen ion excretion
Diarrhoea	Distal (type 1) renal tubular acidosis
Ileostomy	Type 4 renal tubular acidosis (aldosterone deficiency)
Ureterosigmoidostomy	Increased HCl production
Increased renal bicarbonate loss	Ammonium chloride ingestion
Acetazolamide therapy	Increased catabolism of lysine, arginine
Proximal (type 2) renal tubular acidosis	
Hyperparathyroidism	
Tubular damage, e.g. drugs, heavy metals, paraproteins	

Table 13.22 Features of hyporeninaemic hypoaldosteronism (type 4 renal tubular acidosis)

Hyperkalaemia
(in the absence of drugs known to cause hyperkalaemia)
Low plasma bicarbonate and hyperchloraemia
Normal ACTH stimulation test (p. 944)
Low basal 24-hour urinary aldosterone
Subnormal response of plasma renin and plasma aldosterone to stimulation
Samples taken over 2 h supine and again after 40 mg furosemide (80 mg if creatinine >120 $\mu\text{mol/L}$) and 4 h upright posture
Correction of hyperkalaemia by fludrocortisone 0.1 mg daily

Table 13.23 Causes of distal renal tubular acidosis (type 1 RTA)

Primary	Drugs and toxins
Idiopathic	Amphotericin B
Genetic	Lithium carbonate
Marfan's syndrome	NSAIDs
Ehlers-Danlos syndrome	Lead
Sickle cell anaemia	Autoimmune diseases
Nephrocalcinosis	Sjögren's syndrome ^a
Chronic hypercalcaemia	Thyroiditis
Medullary sponge kidney	Autoimmune hepatitis
Hypergammaglobulinaemic states	Primary biliary cirrhosis
Amyloidosis ^a	Systemic lupus erythematosus
Cryoglobulinaemia	Renal transplant rejection^a
Chronic liver disease	

^aMay also cause proximal renal tubular acidosis.

patients have sensorineural deafness, and this is associated with a loss of function mutation in the H⁺-ATPase at the apical surface of intercalated cells.

Treatment is with sodium bicarbonate, potassium supplements and citrate. Thiazide diuretics are useful by causing volume contraction and increased proximal sodium bicarbonate reabsorption.

Urinary anion gap

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

$$\text{URINARY ANION GAP} = \{\text{urinary } [\text{Na}^+] + \text{urinary } [\text{K}^+]\} - \text{urinary } [\text{Cl}^-].$$

This calculation can be used to distinguish the normal anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkali loss) from that caused by distal renal tubular acidosis. In both disorders, the plasma [K⁺] is characteristically low. In patients with renal tubular acidosis, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidaemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea.

Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea, regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal renal tubular acidosis, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal renal tubular acidosis.

Metabolic acidosis with a high anion gap

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small, but unmeasured quantities, such as lactate, or an exogenous acid. Causes of a high-anion-gap acidosis are given in Table 13.24.

Uraemic acidosis

Kidney disease causes acidosis in several ways. Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H⁺ in the urine. In addition, tubular disease may cause bicarbonate wasting. Acidosis is a particular feature of those types of CKD in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

Chronic acidosis is most often caused by chronic kidney disease, where there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Uraemic acidosis should be corrected because of these effects on growth, muscle turnover and bones. Oral sodium bicarbonate 2–3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L, but may contribute to sodium overload. Calcium carbonate improves acidosis and

Practical Box 13.1

Diagnosis of renal tubular acidosis

Plasma HCO₃⁻ <21 mmol/L, urine pH >5.3 = renal tubular acidosis.

To differentiate between proximal (very rare) and distal (rare) requires bicarbonate infusion test

Plasma HCO₃⁻ >21 mmol/L but suspicion of partial renal tubular acidosis (e.g. nephrocalcinosis-associated diseases): **acid load test** required as follows:

- Give 100 mg/kg ammonium chloride by mouth
- Check urine pH hourly and plasma HCO₃⁻ at 3 h
- Plasma HCO₃⁻ should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic)
- If urine pH remains >5.3 despite a plasma HCO₃⁻ of 21 mmol/L, the diagnosis is confirmed

Type 1 ('distal') renal tubular acidosis

This is due to a failure of H⁺ excretion in the distal tubule (Table 13.23). It consists of:

- Acidosis
- Hypokalaemia (few exceptions)
- Inability to lower the urine pH below 5.3 despite systemic acidosis
- Low urinary ammonium production.

These features may be present only in the face of increased acid production; hence the need for an acid load test in diagnosis (Practical Box 13.1). Other features include:

- Low urinary citrate (owing to increased citrate absorption in the proximal tubule where it can be converted to bicarbonate)
- Hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections. *Osteomalacia* is caused by buffering of H⁺ by Ca²⁺ in bone, resulting in depletion of calcium from bone. *Renal stone formation* is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation), and alkaline urine (which favours precipitation of calcium phosphate). *Recurrent urinary infections* are caused by renal stones.

Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. In the autosomal recessive distal RTA, a substantial proportion of

Table 13.24 Causes of metabolic acidosis with an increased anion gap

Kidney failure (serum sulphate and phosphate)
Accumulation of organic acids
Lactic acidosis
L-lactic
Type A – anaerobic metabolism in tissues
Hypotension/cardiac arrest
Sepsis
Poisoning, e.g. ethylene glycol, methanol
Type B – decreased hepatic lactate metabolism deficiency (decreased pyruvate dehydrogenase activity)
Metformin accumulation (chronic kidney disease)
Haematological malignancies
Rare inherited enzyme defects
D-lactic (fermentation of glucose in bowel by abnormal bowel flora, complicating abnormal small bowel anatomy, e.g. blind loops)
Ketoacidosis
Insulin deficiency
Alcohol excess
Starvation
Exogenous acids
Salicylate

also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage kidney failure is usually fully corrected by adequate dialysis.

Lactic acidosis

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues ('type A') or a metabolic abnormality, such as drug-induced ('type B') (Table 13.24). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock. Significant acidosis can occur despite a normal blood pressure and $P_a\text{CO}_2$, owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Diabetic ketoacidosis (see p. 1017)

There is a high-anion-gap acidosis due to the accumulation of acetoacetic and hydroxybutyric acids, owing to increased production and some reduced peripheral utilization.

Mixed metabolic acidosis

Both types of acidosis may co-exist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to renal failure and lactic acidosis as a result of hypovolaemia.

Clinical features

Clinically, the most obvious effect is stimulation of respiration, leading to the clinical sign of 'air hunger', or Kussmaul respiration. Interestingly, patients with profound hyperventilation may not complain of breathlessness, although in others it may be a presenting complaint.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal (see p. 870). Cardiovascular dysfunction is common in acidotic patients, although it is often difficult to dissociate the numerous possible causes of this. Acidosis is negatively inotropic. Severe acidosis also

causes venoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion ('type A'), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In 'type B' lactic acidosis, treatment is that of the underlying disorder; e.g.:

- Insulin in diabetic ketoacidosis
- Treatment of methanol and ethylene glycol poisoning with ethanol
- Removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO_2 production and will therefore correct acidosis only if ventilation can be increased to remove the added CO_2 load.
- The increased amounts of CO_2 generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate intravenously) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when $[\text{H}^+]$ is above 126 nmol/L (pH <6.9), using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2–3 h with electrolyte and pH monitoring. Intravenous sodium lactate should never be given.

Metabolic alkalosis

Metabolic alkalosis is common, comprising half of all the acid–base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics, and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is >7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Table 13.25).

Table 13.25 Causes of metabolic alkalosis**Chloride depletion**

Gastric losses: vomiting, mechanical drainage, bulimia
 Chloruretic diuretics, e.g. bumetanide, furosemide, chlorothiazide, metolazone
 Diarrhoeal states: villous adenoma, congenital chloridorrhoea
 Cystic fibrosis (high sweat chloride)

Potassium depletion/mineralocorticoid excess

Primary aldosteronism
 Secondary aldosteronism
 Apparent mineralocorticoid excess
 Primary deoxycorticosterone excess: 11 α - and 17 α -hydroxylase deficiencies
 Drugs: liquorice (glycyrrhizic acid) as a confection or flavouring, carbenoxolone
 Liddle's syndrome
 Bartter's and Gitelman's syndromes and their variants
 Laxative abuse, clay ingestion

Hypercalcaemic states

Hypercalcaemia of malignancy
 Acute or chronic milk-alkali syndrome

Others

Amoxicillin, penicillin therapy
 Bicarbonate ingestion: massive or with kidney disease
 Recovery from starvation
 Hypoalbuminaemia

The most common group is due to chloride depletion which can be corrected without potassium repletion. The other major grouping is that due to potassium depletion, usually with mineralocorticoid excess. Metabolic alkalosis due to both potassium and chloride depletion also occurs.

Chloride may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see p. 370) or gastric outflow obstruction these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

Chloruretic agents all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

- Diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion
- Extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion
- Potassium depletion augments bicarbonate reabsorption in the proximal tubule and
- Stimulates ammonia production which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears

to be the major nephron site for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α -intercalated cells in the cortical collecting duct do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in *hypokalaemia* is generated primarily by an increased intracellular shift of hydrogen ion causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production with increased obligate net acid excretion. However, the role of intracellular acidosis is supported by the correction of the alkalosis by infusion of potassium without any suppression of renal net excretion. The correction is assumed to occur by the movement of potassium into and hydrogen ion out of the cell, which titrates extracellular fluid bicarbonate.

Milk-alkali syndrome in which both bicarbonate and calcium are ingested produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR. Cationic antibiotics in high doses can cause alkalosis by obligatory bicarbonate loss in the urine.

Clinical features

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume or potassium depletion. Tetany (see p. 997), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

Treatment**Chloride-responsive metabolic alkalosis**

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation – sodium, potassium or proton – is dependent on the assessment of extracellular fluid volume status (see p. 646), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion co-exist then isotonic saline solution is appropriate therapy.

In the clinical settings of fluid overload, saline is contraindicated. In such situations, intravenous use of hydrochloric acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.

Chloride-resistant metabolic alkalosis

Metabolic alkalosis due to potassium depletion is managed by the correction of the underlying cause (see *hypokalaemia*). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

ESSENTIAL ANATOMY, PHYSIOLOGY AND EMBRYOLOGY OF THE HEART

Introduction

Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking in myofibril components. They have the ability to generate electrical impulses which are then conducted to the myocytes, leading to contraction by a process known as excitation-contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as 'autoregulation'; blood vessel control is, however, complex involving additional local and central mechanisms.

The conduction system of the heart

The sinus node

The sinus node is a complex spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 14.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential ('the pacemaker potential'), the most significant of which is a small influx of sodium ions into the cells. This small sodium current

Figure 14.1 The conducting system of the heart.

Figure 14.2 Myocardial action potentials. I_b , background inward sodium current; I_f , 'funny' current; I_{CaT} , transient (or 'T' type) and I_{CaL} , long-lasting (or 'L' type) calcium channels; I_{Na} , inward sodium current; I_{To} , transient outward potassium current; I_{K1} , inward rectifier potassium current; I_K delayed rectifier potassium current.

Figure 14.3 The 'complete' cardiac cell. (1) Spontaneous depolarization in sinus node cells due to sodium (Na) influx through the 'funny' current generates the 'pacemaker' potential. (2) This activates other atrial and ventricular myocytes, triggering action potentials and activating L-type calcium (Ca) channels in the surface and transverse tubule membranes (at top and bottom of figure). (3) The resulting Ca influx acts on Ca-induced Ca release channels (RyR2) on the sarcoplasmic reticulum (SR), resulting in release of stored Ca, which acts on actin and myosin fibrils, resulting in contraction. Ca reuptake pumps in the SR, regulated by phospholamban, replenish the stores; various exchange pumps also expel Ca from the cell. (4) Autonomic input has either a positive chronotropic/inotropic effect (β_1 receptors) or a negative chronotropic/inotropic effect (muscarinic receptors).

has two components: the background inward current (I_b) and the 'funny' (I_f) current (or pacemaker current) (Fig. 14.2). The term 'funny' current denotes ionic flow through channels activated in *hyperpolarized* cells (-60 mV or greater), unlike other time- and voltage-dependent channels activated by *depolarization*. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e. sympathetic and parasympathetic input), stretch, temperature, hypoxia, blood pH and in response to other hormonal influences (e.g. tri-iodothyronine and serotonin).

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial and subsequently the ventricular myocytes. These cells have a different action potential from that of sinus node cells (Fig. 14.2). Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open 'inward rectifier' channels (I_{K1}); at this stage sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated,

fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of 'transient outward' potassium channels.

The plateau phase which follows is unique to myocytes and results from a small, but sustained inward calcium current through L-type calcium channels (I_{CaL}) lasting 200–400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 14.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels (I_K) repolarizing the membrane. Atrial tissue is activated like a 'forest fire', but the activation peters out when the insulating layer between the atrium and the ventricle – the annulus fibrosus – is reached. Controversy exists about whether impulses from the sinoatrial (SA) node travel over specialized conducting 'pathways' or over ordinary atrial myocardium.

The atrioventricular node, His bundle and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The **right bundle branch** continues down the right side of the interventricular septum to the apex, from where it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. The **main left bundle branch** is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials largely produced by slow transmembrane calcium flux. In the atria, ventricles and His-Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

The cellular basis of myocardial contraction – excitation-contraction coupling

Each myocyte, approximately 100 μm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 14.4). A sarcomere (which is the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z

bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain ATPase, which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure, with another molecule, tropomyosin, in the grooves of the actin helix, and a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential by calcium ions entering the cell and by being mobilized from the sarcoplasmic reticulum through the ryanodine receptor (RyR2) calcium-release channel. RyR2 activity is regulated by the protein calstabin 2 (see p. 770) and nitric oxide. The force of cardiac muscle contraction ('inotropic state') is thus regulated by the influx of calcium ions into the cell through calcium channels (Fig. 14.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling's law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that is moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 14.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known

Figure 14.4 Schematic diagram showing the structure of a myofibril within a myocyte. The myofibrils are made up of a series of sarcomeres joined at the Z line.

Figure 14.5 The Frank-Starling mechanism, showing the effect on ventricular contraction of alteration in filling pressures and outflow impedance in the normal, failing and sympathetically stimulated ventricle.

as 'Starling's law of the heart' or the 'Frank-Starling relationship'. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure \times stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (Fig. 14.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres as well as the conduction system. β_1 -Receptors predominate in the heart with both epinephrine (adrenaline) and norepinephrine (noradrenaline) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M_2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

β_1 -Adrenergic stimulation enhances Ca^{2+} flux in the myocyte and thereby strengthens the force of contraction (Fig. 14.3). Binding of catecholamines, e.g. norepinephrine (noradrenaline), to the myocyte β_1 -adrenergic receptor stimulates membrane-bound adenylate kinases. These enzymes enhance production of cyclic adenosine monophosphate (cAMP) that activates intracellular protein kinases, which in turn phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. β_1 -Adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the sarcoplasmic reticulum (SR) is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca^{2+} uptake by the SR ATPase pump (Fig. 14.3). However, β_1 -adrenergic activation of protein kinase phosphorylates PL, and blunts its inhibitory effect. The subsequently greater uptake of Ca^{2+} ions by the SR hastens Ca^{2+} removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin-myosin interaction, and further enhances myocyte relaxation.

The cardiac cycle

The cardiac cycle (Fig. 14.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG) followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and shortly thereafter right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures, and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure.

Figure 14.6 The cardiac cycle.

Figure 14.7 Pressure-volume loop. AB, diastole: ventricular filling; BC systole: isovolumetric ventricular contraction; CD, systole: ventricular emptying; DA, diastole: isovolumetric ventricular relaxation.

Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be graphically depicted as the relationship between the pressure and volume of the ventricle. This is shown in Figure 14.7, which illustrates the changing pressure-volume relationships in response to increased contractility and to exercise.

The coronary circulation

The coronary arterial system (Fig. 14.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. These arteries are unique in that they fill during diastole, when not occluded by valve cusps and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels

Figure 14.8 (a) Diagram of the normal coronary arterial anatomy. (b) Angiogram of non-dominant right coronary system. (c) Angiogram of dominant left coronary system from the same patient. Right anterior oblique projection.

that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.

Within 2.5 cm of its origin from the left coronary sinus, the left main coronary divides into the left anterior descending artery and the circumflex artery. The left anterior descending artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left AV groove and gives off branches to the left atrium and the left ventricle (marginal branches).

The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore, disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery and disease in this vessel can cause significant myocardial dysfunction.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart by tiny veins, but the majority returns by veins which accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.

Blood vessel control and functions of the vascular endothelium

In functional terms, the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired, or in various pathological states, e.g. haemorrhage, endocrine control of blood vessels mediated through epinephrine (adrenaline), angiotensin and vasopressin takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops and vice versa. This process of *autoregulation* is a consequence of:

- **The Bayliss myogenic** response – the ability of blood vessels to constrict when distended
- **The vasodilator washout** effect – the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitric oxide (NO), prostacyclin (PGI₂), endothelin, endothelial-derived hyperpolarizing factor (ERHF), adhesion molecules, vascular endothelial growth factor (VEGF)) and has enzymes located on the surface controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles:

Vasomotor control

Nitric oxide is a diffusible gas with a very short half-life, produced in endothelial cells from the amino acid L-arginine

via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 14.9). It is produced in response to various stimuli (Table 14.1), triggering vascular smooth muscle relaxation through activation of guanylate cyclase, leading to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure and thrombosis. NO is also the neurotransmitter in various 'nitroergic' nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE₅) inhibitors, prevent the breakdown of cGMP and promote vasodilatation.

PGI₂ is synergistic to NO and also plays a role in the local regulation of vasomotor tone.

Endothelin is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress, i.e. the stress exerted on the vessel wall by the flowing blood, and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.

Angiotensin-converting enzyme located on the endothelial cell membrane converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II which has vasoconstrictor properties and leads to aldosterone release (Fig. 12.5). Aldosterone promotes sodium absorption from the kidney and together with the angiotensin-induced vasoconstriction provides haemodynamic stability.

Other factors which influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor XIIa) and serotonin released by platelets.

Figure 14.9 Nitric oxide (NO): the stimulus for production and function of NO. Various stimuli lead to the production of NO via cytoplasmic calcium/calmodulin. NO triggers smooth muscle relaxation via the activation of guanylyl cyclase. ROC, receptor-operated Ca²⁺ channel; SAC, stretch-activated Ca²⁺ channel; IP₃, inositol triphosphate; ER, endoplasmic reticulum; GTP, guanine triphosphate; cGMP, cyclic guanine monophosphate.

Table 14.1 Some of the products and functions of the vascular endothelium

Endothelial product	Function(s)	Stimulus
Nitric oxide	Vasodilation Inhibits platelet aggregation Inhibits transcription of adhesion molecules Inhibits vascular smooth muscle proliferation	Shear stress, e.g. induced by exercise Agonists: thrombin, acetylcholine, endothelin, bradykinin, serotonin, substance P Inflammation/endotoxin shock
Prostacyclin (PGI ₂)	Vasodilation Inhibits platelet aggregation	Agonist: thrombin Inflammation
Prostanoids	Vasoconstriction	Hypoxia
Endothelin	Vasoconstriction	Thrombin, angiotensin II, vasopressin Hypoxia Note: Inhibited by shear stress
Endothelial-derived hyperpolarizing factor	Vasodilation	Agonists: bradykinin, acetylcholine
Angiotensin-converting enzyme	Vasoconstriction	Expressed naturally
von Willebrand factor	Promotes platelet aggregation Stabilizes factor VIII	Agonists: thrombin, epinephrine (adrenaline)
Adhesion molecules P, L, E selectins ICAM, VCAM, PECAM	Margination of white blood cells (WBCs) Binding and diapedesis of WBCs into vessel wall	Inflammatory mediators: histamine, thrombin, TNF, IL-6
Vascular endothelial growth factor (VEGF)	Angiogenesis Vasodilation Increased vascular permeability	Pregnancy Hypoxia Inflammation, e.g. rheumatoid arthritis Trauma Tumours

ICAM, intracellular adhesion molecule; VCAM, vascular cell adhesion molecule, PECAM, platelet/endothelial cell adhesion molecule; TNF, tumour necrosis factor; IL, interleukin.

Anti- and pro-thrombotic mechanisms

PGI_2 , produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase, inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI_2 synthesis, unlike higher doses. Other antithrombotic agents such as clopidogrel (ADP receptor antagonist) and glycoprotein IIb/IIIa inhibitors achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI_2 is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting, heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (p. 414).

Modulation of immune responses

In response to various inflammatory mediators, the vascular endothelium expresses various so-called ‘adhesion molecules’ which promote leucocyte attraction, adhesion and infiltration into the blood vessel wall (Chapter 3).

Regulation of vascular cell growth

The endothelial cells are also responsible for the development of new blood vessels (‘angiogenesis’) in the placenta, wound healing, tissue repair and tumour growth. This process is facilitated by VEGF.

SYMPTOMS OF HEART DISEASE

The following symptoms occur with heart disease:

- Chest pain
- Breathlessness
- Palpitations
- Syncope
- Fatigue
- Peripheral oedema.

The severity of cardiac symptoms or fatigue is classified according to the New York Heart Association (NYHA) grading of cardiac status (see Table 14.19). The differential diagnosis of chest pain is given in Table 14.2.

Table 14.2 Differential diagnosis of chest pain

Central	Lateral/peripheral
Cardiac	Pulmonary
Ischaemic heart disease (infarction or angina)	Infarction
Coronary artery spasm	Pneumonia
Pericarditis/myocarditis	Pneumothorax
Mitral valve prolapse	Lung cancer
Aortic aneurysm/dissection	Mesothelioma
Non-cardiac	Non-pulmonary
Pulmonary embolism	Bornholm disease (epidemic myalgia)
Oesophageal disease (see Box 6.3)	Herpes zoster
Mediastinitis	Trauma (ribs/muscular)
Costochondritis (Tietze disease)	
Trauma (soft tissue, rib)	

Central chest pain

This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia. Types of pain include:

- Retrosternal heavy or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates – **angina** (p. 729)
- Similar pain at rest – **acute coronary syndrome** (p. 734)
- Severe tearing chest pain radiating through to the back – **aortic dissection** (p. 787)
- Sharp central chest pain that is worse with movement or respiration but relieved with sitting forward – **pericarditis pain** (p. 774)
- Sharp stabbing left submammary pain associated with anxiety – **Da Costa’s syndrome**.

Dyspnoea

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate the lungs. **Tachypnoea** (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

Orthopnoea refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

Paroxysmal nocturnal dyspnoea (PND) is when a patient is woken from sleep fighting for breath. It is due to the same mechanisms as orthopnoea. However, as sensory awareness is reduced whilst asleep, the pulmonary oedema can become quite severe before the patient is awoken.

Hyperventilation with alternating episodes of apnoea (**Cheyne–Stokes respiration**) occurs in severe heart failure.

Central sleep apnoea syndrome (CSAS). If hypopnoea occurs rather than apnoea, the phenomenon is termed ‘periodic breathing’, but the two variations are known together as CSAS. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease. The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, p. 818) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias, including non-sustained ventricular tachycardia, hypertension and stroke. Patients with CSAS have a worse prognosis compared to similar patients without CSAS.

Palpitations

These represent an increased awareness of the normal heart beat or the sensation of slow, rapid or irregular heart rhythms. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

- **Premature beats (ectopics)** are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful as the heart has had a longer

Significant pauses (in rhythm)
Artificial pacemaker failure

diastolic period and therefore is filled with more blood before this beat.

- **Paroxysmal tachycardias** (see p. 698) are felt as a sudden racing heart beat.
- **Bradycardias** (p. 702) may be appreciated as slow, regular, heavy or forceful beats. Most often, however, they are simply not sensed. All palpitations can be graded by the NYHA cardiac status (see Table 14.19).

Syncope

Syncope is a transient loss of consciousness due to inadequate cerebral blood flow. The cardiovascular causes are listed in Table 14.3.

Vascular:

- **A vasovagal attack** is a simple faint and is the most common cause of syncope. The mechanism begins with peripheral vasodilatation and venous pooling of blood, leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which in turn stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These in turn trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e. further vasodilatation and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.
- **Postural (orthostatic) hypotension** is a drop in systolic blood pressure of 20 mmHg or more on standing from a sitting or lying position. Usually, reflex vasoconstriction prevents a drop in pressure but if this is absent or the patient is fluid depleted or on *vasodilating or diuretic drugs*, hypotension occurs.
- **Postprandial hypotension** is a drop in systolic blood pressure of ≥ 20 mmHg or the systolic blood pressure drops from above 100 mmHg to under 90 mmHg within 2 hours of eating. The mechanism is unknown but may be due to pooling of blood in the splanchnic vessels. In normal subjects, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output.

- **Micturition syncope** refers to loss of consciousness whilst passing urine.
- **Carotid sinus syncope** occurs when there is an exaggerated vagal response to carotid sinus stimulation, provoked by wearing a tight collar, looking upwards or turning the head.

Obstructive. The obstructive cardiac causes listed in Table 14.3 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

Arrhythmias. *Stokes–Adams attacks* (p. 700) are a sudden loss of consciousness unrelated to posture and due to intermittent high-grade AV block, profound bradycardia or ventricular standstill. The patient falls to the ground without warning, is pale and deeply unconscious. The pulse is usually very slow or absent. After a few seconds the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae, but patients may injure themselves during falls. Occasionally a generalized convulsion may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. It is due to poor sleep, a direct side-effect of medication, particularly beta-blockers, electrolyte imbalance due to diuretic therapy and as a systemic manifestation of infection such as endocarditis.

Peripheral oedema

Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin-angiotensin-aldosterone system (p. 566). This leads to dependent pitting oedema.

EXAMINATION OF THE CARDIOVASCULAR SYSTEM**General examination**

General features of the patient's wellbeing should be noted as well as the presence of conjunctival pallor, obesity, jaundice and cachexia.

- **Clubbing** (p. 799) is seen in congenital cyanotic heart disease, particularly Fallot's tetralogy and also in 10% of patients with subacute infective endocarditis.
- **Splinter haemorrhages.** These small, subungual linear haemorrhages are frequently due to trauma, but are also seen in infective endocarditis.
- **Cyanosis** is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is less than 85%. *Central cyanosis* (p. 799) is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt. *Peripheral cyanosis* is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation, e.g. Raynaud's, p. 788.

The arterial pulse

The first pulse to be examined is the right radial pulse. A delayed femoral pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

Pulse rate

The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed.

Rhythm

The rhythm is regular except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

- **Premature beats** occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.
- **Atrial fibrillation** produces an irregularly irregular pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

Character of pulse

- **Carotid pulsations** are not normally apparent on inspection of the neck but may be visible (Corrigan's sign) in conditions associated with a large-volume pulse, including high output states (such as thyrotoxicosis, anaemia or fever) and in aortic regurgitation.
- A **'collapsing' or 'water hammer' pulse** (Fig. 14.10) is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmar aspect of four

fingers while elevating the patient's arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.

- A **small-volume pulse** is seen in cardiac failure, shock and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias.
- A **plateau pulse** is small in volume and slow in rising to a peak due to aortic stenosis (Fig. 14.10).
- **Alternating pulse (pulsus alternans)**. This is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg (Fig. 14.10).
- **Bigeminal pulse (pulsus bigeminus)**. This is due to a premature ectopic beat following every sinus beat. The rhythm is not regular (Fig. 14.10) because every weak pulse is premature.
- **Pulsus bisferiens** (Fig. 14.10). This is a pulse that is found in hypertrophic cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the 'percussion' wave produced by the transmission of the left ventricular pressure in early systole. The second peak is the 'tidal' wave caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed from emptying completely, the tidal wave occurs in late systole. The result is a palpable double pulse.
- **Dicrotic pulse** (Fig. 14.10) results from an accentuated dicrotic wave. It occurs in sepsis, hypovolaemic shock and after aortic valve replacement.
- **Paradoxical pulse**. Paradoxical pulse is a misnomer, as it is actually an exaggeration of the normal pattern. In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is <10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma) there is an increased negative intrathoracic pressure on inspiration which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur through a similar mechanism in constrictive pericarditis but is less common.

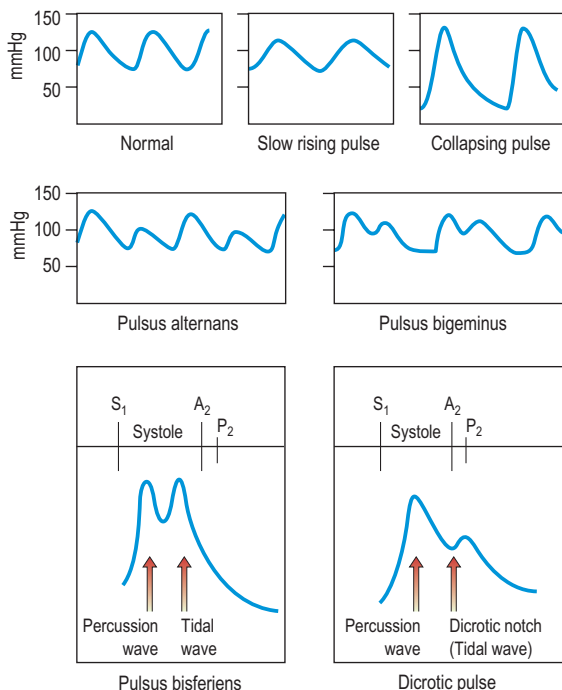

Figure 14.10 Arterial waveforms. A2, aortic component of the second heart sound; P2, pulmonary component of the second heart sound; S1, first heart sound.

The blood pressure

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. How to take the blood pressure is outlined in Practical Box 14.1.

Jugular venous pressure

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the

Practical Box 14.1

Taking the blood pressure

Use a properly calibrated machine.

1. The blood pressure is taken in the (right) arm with the patient relaxed and comfortable.
2. The sphygmomanometer cuff is wrapped around the upper arm with the inflation bag placed over the brachial artery.
3. The cuff is inflated until the pressure exceeds the arterial pressure – when the radial pulse is no longer palpable.
4. The diaphragm of the stethoscope is positioned over the brachial artery just below the cuff.
5. The cuff pressure is slowly reduced until sounds (Korotkoff sounds) can be heard (*phase 1*). This is the systolic pressure.
6. The pressure is allowed to fall further until the Korotkoff sounds become suddenly muffled (*phase 4*).
7. The pressure is allowed to fall still further until they disappear (*phase 5*).

The diastolic pressure is usually taken as *phase 5* because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear (*phase 2*) and reappear (*phase 3*) between the systolic and diastolic pressures. Do not mistake *phase 2* for the diastolic pressure or *phase 3* for the systolic pressure.

Practical Box 14.2

Measurement of jugular venous pressure

- The patient is positioned at about 45° to the horizontal (between 30° and 60°), wherever the top of the venous pulsation can be seen in a good light.
- The jugular venous pressure is measured as the vertical distance between the manubriosternal angle and the top of the venous column.
- The normal jugular venous pressure is usually <3 cmH₂O, which is equivalent to a right atrial pressure of 8 cmH₂O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.
- The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).
- Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the JVP more visible (hepatojugular reflux).

internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied upon because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can only be used if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure (JVP)

See Practical Box 14.2.

Elevation of the jugular venous pressure occurs in *heart failure*. It is also produced by an elevated jugular venous pressure which occurs in constrictive pericarditis and cardiac tamponade (increases in inspiration – *Kussmaul's sign*), renal disease with salt and water retention, overtransfusion or excessive infusion of fluids, congestive cardiac failure and superior vena cava obstruction. A reduced jugular venous pressure occurs in hypovolaemia.

The jugular venous pressure wave

This consists of three peaks and two troughs (Fig. 14.11). The peaks are described as **a**, **c** and **v** waves and the troughs are known as **x** and **y** descents:

Figure 14.11 Jugular venous waveforms.

- **The a wave** is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
- **The x descent** occurs when atrial contraction finishes.
- **The c wave** occurs during the **x** descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.
- **The v wave** occurs with venous return filling the right atrium. Giant **v** waves occur in tricuspid regurgitation.
- **The y descent** follows the **v** wave when the tricuspid valve opens. A steep **y** descent is seen in constrictive pericarditis and tricuspid incompetence.

Examination of the precordium

- With the patient at 45°, the cardiac apex is located in the 5th intercostal space mid-clavicular line. Left ventricular dilatation will displace the apex downwards and laterally. It may be impalpable in patients with emphysema, obesity, pericardial or pleural effusions.
- **A tapping apex** is a palpable first sound and occurs in mitral stenosis.
- **A vigorous apex** may be present in diseases with volume overload, e.g. aortic regurgitation.
- **A heaving apex** may occur with left ventricular hypertrophy – aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.
- **A double pulsation** may occur in hypertrophic cardiomyopathy.
- **A sustained left parasternal heave** occurs with right ventricular hypertrophy or left atrial enlargement.
- **A palpable thrill** may be felt overlying an abnormal cardiac valve, e.g. systolic thrill with aortic stenosis.

Auscultation

The *bell* of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis). The *diaphragm* is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks and opening snaps). The areas of auscultation are described in (Fig. 14.12). Left-sided valve murmurs may be more prominent in

Figure 14.12 Heart auscultation. A, aortic area 2nd ICS right sternal edge. P, pulmonary area 2nd ICS left sternal edge. M, mitral area 5th ICS, mid-clavicular line. T, tricuspid area 3rd to 5th ICS, left sternal edge.

expiration and right-sided in inspiration. Mitral murmurs may be more audible with the patient reclining to the left.

First heart sound (S1)

This is due to mitral and tricuspid valve closure. A loud S1 occurs in thin people, hyperdynamic circulation, tachycardias and mild-moderate mitral stenosis. A soft S1 occurs in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis, mitral or tricuspid regurgitation, heart failure, shock, bradycardias and first-degree block.

Second heart sound (S2)

This is due to aortic and pulmonary valve closure. Physiological splitting of S2 occurs during inspiration in children and young adults.

Third and fourth heart sounds

These are pathological:

- **A third heart sound** is due to rapid ventricular filling and is present in heart failure.
- **A fourth heart sound** occurs in late diastole and is associated with atrial contraction.

Either, singly or together, will produce a gallop rhythm.

Heart murmurs

These are due to turbulent blood flow and occur in hyperdynamic states or with abnormal valves. (Listen online in Student Consult.) Innocent or flow murmurs are soft, early systolic, short and non-radiating. They are heard frequently in children and young adults. Heart murmurs can be graded with the following scale:

- 1/6 very faint; not always heard in all positions
- 2/6 quiet but not difficult to hear
- 3/6 moderately loud
- 4/6 loud \pm thrills
- 5/6 very loud \pm thrills; are heard with stethoscope partly off chest
- 6/6 is heard with stethoscope completely off chest; \pm thrills

The individual murmurs are discussed under valve disease, page 740.

Figure 14.13 Diagrams to show the heart silhouette on the chest X-ray, measurements of the cardiothoracic ratio (CTR) and the location of the cardiac valves. The dotted line is an arbitrary line from the left hilum to the right cardiophrenic angle: a calcified aortic valve is seen above this line. $CTR = (C/T) \times 100\%$; normal CTR $<50\%$.

CARDIAC INVESTIGATIONS

Blood tests

Routine haematology, urea/creatinine and electrolytes, liver biochemistry, cardiac enzymes, thyroid function and brain natriuretic peptides (BNP).

Chest X-ray

Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray film to minimize magnification with respect to the thorax. A lateral may give additional information if the PA is abnormal. The cardiac structures and great vessels that can be seen on these X-rays are indicated in Figure 14.13. An antero-posterior (AP) view is only taken in an emergency.

Heart size

Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio). The cardiothoracic ratio (CTR) is usually $<50\%$, except in neonates, infants, athletes and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter of more than 15.5 cm is abnormal. Pericardial effusion or cardiac dilatation causes an increase in the ratio.

A pericardial effusion produces a globular heart (see Fig. 14.115, p. 775). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific (p. 776).

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

Left atrial dilatation. This results in prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 14.14). On a

Figure 14.14 Plain PA chest X-ray of a patient with mixed mitral valve disease. The left atrium is markedly enlarged (a). Note the large bulge on the left heart border (left atrium). The 'double shadow' (border of the right and left atria) (b) is on the right side of the heart. There is cardiac (left ventricular) enlargement due to mitral regurgitation.

lateral chest X-ray an enlarged left atrium bulges backwards, impinging on the oesophagus.

Left ventricular enlargement. This results in an increase in the CTR and a smooth elongation and increased convexity of the left heart border.

Right atrial enlargement. This results in the right border of the heart projecting into the right lower lung field.

Right ventricular enlargement. This results in an increase of the CTR and an upward displacement of the apex of the heart because the enlarging right ventricle pushes the left ventricle leftwards, upwards and eventually backwards. Differentiation of left from right ventricular enlargement may be difficult from the shape of the left heart border alone, but the lateral view shows enlargement anteriorly for the right ventricle and posteriorly for the left ventricle.

Ascending aortic dilatation or enlargement. This is seen as a prominence of the aortic shadow to the right of the mediastinum between the right atrium and superior vena cava.

Dissection of the ascending aorta. This is seen as a widening of the mediastinum on chest X-ray but an ultrasound/magnetic resonance imaging (MRI) should be performed.

Enlargement of the pulmonary artery. Enlargement of the pulmonary artery in pulmonary hypertension, pulmonary artery stenosis and left-to-right shunts produces a prominent bulge on the left-hand border of the mediastinum below the aortic knuckle.

Calcification

Calcification in the cardiovascular system occurs because of tissue degeneration. Calcification is visible on a lateral or a penetrated PA film, but is best studied with computed tomography (CT) scanning.

Lung fields

Pulmonary plethora results from left-to-right shunts (e.g. atrial or ventricular septal defects). It is seen as a general increase in the vascularity of the lung fields and as an increase in the size of hilar vessels (e.g. in the right lower

lobe artery), which normally should not exceed 16 mm diameter.

Pulmonary oligoemia is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot's tetralogy.

Pulmonary hypertension may result from pulmonary embolism, chronic lung disease or chronic left heart disease, e.g. left ventricular failure or mitral valve disease such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to X-ray features of these conditions, the pulmonary arteries are prominent close to the hila but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical. Normal pulmonary capillary pressure is 5–14 mmHg at rest. Mild pulmonary capillary hypertension (15–20 mmHg) produces isolated dilatation of the upper zone vessels.

Interstitial oedema occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and pleural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields.

Alveolar oedema occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (Fig. 14.15) and pleural effusions. Patients with long-standing elevation of the pulmonary capillary pressure have reactive thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.

Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see Fig. 14.2, p. 670). At the body surface these generate potential differences of about 1 mV, and the fluctuations of these potentials create the familiar P-QRS-T pattern. At rest the intracellular voltage of the myocardium is polarized at –90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 in Fig. 14.37, p. 698). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called 'leads' (Fig. 14.16).

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads

Figure 14.15 Acute pulmonary oedema. This pair of chest X-rays were taken from a patient before (a) and after (b) treatment of acute pulmonary oedema. The X-ray taken when the oedema was present demonstrates hilar haziness, Kerley B lines, upper lobe venous engorgement and fluid in the right horizontal interlobar fissure. These abnormalities are resolved on the film taken after successful treatment.

Figure 14.16 The connections or directions that comprise the 12-lead electrocardiogram.

record potentials between points on the chest surface and an average of the three limbs: RA, LA and LL. These are designated V_1 – V_6 and aim to select activity from the right ventricle (V_1 – V_2), interventricular septum (V_3 – V_4) and left ventricle (V_5 – V_6). Note that leads AVR and V_1 are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and V_6 face the lateral wall of the left ventricle. A V_4 on the right side of the chest (V_4R) is occasionally useful (e.g. for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders with output either as a continuous strip or with automatic channel switching. Many ECG machines also

analyse the recordings and print the analysis on the record. Usually the machine interpretation is correct, but many arrhythmias still defy automatic analysis.

The ECG waveform

The shape of the normal ECG waveform (Fig. 14.17) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization, and it is a low-amplitude slow deflection called a *P wave*. The *QRS complex* reflects ventricular activation or depolarization and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the *Q wave*. An initial upward deflection is called an *R wave*. The *S wave* is the last part of ventricular activation.

Figure 14.17 The waves and elaboration of the normal electrocardiogram.

Table 14.4 Normal ECG intervals	
P wave duration	≤0.12 s
PR interval	0.12–0.22 s
QRS complex duration	≤0.10 s
Corrected QT (QT _c)	≤0.44 s in males ≤0.46 s in female
QT _{CB} = QT√ ² (R – R)	Bazett's square root formula
QT _{CF} = QT√ ³ (R – R)	Fridericia's cube root formula

The T wave is another slow and low-amplitude deflection that results from ventricular repolarization.

The PR interval is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node and His–Purkinje system to the ventricle.

The QT interval extends from the start of the QRS complex to the end of the T wave. This interval represents the time taken to depolarize and repolarize the ventricular myocardium. The QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QT_c) for a given heart rate. There are a number of formulae for derivation of QT_c, but the most widely accepted are Bazett's formula and Fridericia's correction (Table 14.4).

An abnormally prolonged QT_c can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of QT interval may be congenital or can occur in many acquired conditions (see Table 14.12, p. 709).

The ST segment is the period between the end of the QRS complex and the start of the T wave. In the normal heart, all cells are depolarized by this phase of the ECG, i.e. the ST segment represents ventricular repolarization.

A normal 12-lead ECG is shown in Figure 14.18, and the normal values for the electrocardiographic intervals are indicated in Table 14.4. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular cavity are usually negative. Detailed patterns depend on the size, shape and rhythm of the heart and the characteristics of the torso.

Cardiac vectors

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

Figure 14.18 A normal 12-lead electrocardiogram.

The mean QRS vector can be calculated from the six standard leads (Fig. 14.19):

- Normal between -30° and $+90^\circ$
- Left axis deviation between -30° and -90°
- Right axis deviation between $+90^\circ$ and $+150^\circ$.

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

Exercise electrocardiography

This is less used than previously (see p. 730) because of its low sensitivity. The ECG is recorded whilst the patient walks or runs on a motorized treadmill. The test is based upon the principle that exercise increases myocardial demand on coronary blood supply, which may be inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, e.g. the Bruce protocol. Recording an ECG after exercise is not an adequate form of stress test. Normally there is little change in the T wave or ST segment during exercise.

The patient's exercise capacity (the total time achieved) will depend on many factors; however, patients who can only exercise for <6 min generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (>1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it is either planar or shows down-sloping depression (Fig. 14.20). Up-sloping depression is a nonspecific finding. The degree of ST segment depression is positively correlated to the degree of myocardial ischaemia.

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it occurs, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in leads V₅ (anterior and lateral ischaemia) or AVF (inferior ischaemia), it

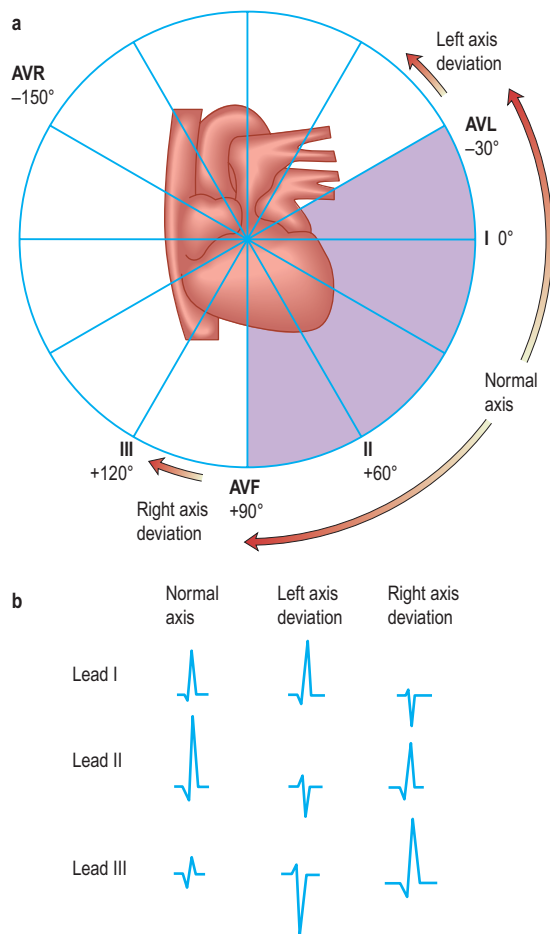

Figure 14.19 Cardiac vectors. (a) The hexaxial reference system, illustrating the six leads in the frontal plane, e.g. lead I is 0° , lead II is $+60^\circ$, lead III is $+120^\circ$. (b) Calculating the direction of the cardiac vector. In the first column the QRS complex with zero net amplitude (i.e. when the positive and negative deflections are equal) is seen in lead III. The mean QRS vector is therefore perpendicular to lead III and is either -150° or $+30^\circ$. Lead I is positive, so the axis must be $+30^\circ$, which is normal. In left axis deviation (second column) the main deflection is positive (R wave) in lead I and negative (S wave) in lead III. In right axis deviation (third column) the main deflection is negative (S wave) in lead I and positive (R wave) in lead III. The frontal plane QRS axis is normal only if the QRS complexes in leads I and II are predominantly positive.

Figure 14.20 Electrocardiographic changes during exercise test. Upper trace: significant horizontal ST segment depression during exercise. Lower trace: ST elevation during exercise.

is best to record a full 12-lead ECG. During an exercise test the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes and further testing is required in these patients. Use of the exercise test in angina is described on page 682.

24-Hour ambulatory taped electrocardiography

This records transient changes such as a brief paroxysm of tachycardia, an occasional pause in the rhythm, or intermittent ST segment shifts (Fig. 14.21). A conventional 12-lead ECG is recorded in less than a minute and usually samples less than 20 complexes. In a 24-hour period, over 100 000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called 'Holter' electrocardiography after its inventor.

Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.

A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

Other tests

Non-invasive methods that make use of digitalized Holter recordings to identify increased risk of ventricular arrhythmias include assessment of heart rate variability, signal averaged ECG (SAECG) and T wave alternans.

Heart rate variability (HRV) can be assessed from a 24 hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged from hospital following myocardial infarction.

Signal-averaged ECG (SAECG) is a technique that requires amplification and averaging of abnormal low-amplitude signals which occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.

T wave alternans (TWA) is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.

Tilt testing

Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table which is tilted to $+60^\circ$ to the vertical for ≥ 45 minutes. The ECG and blood pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 14.22) and pre-syncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible. The overall sensitivity, specificity and reproducibility is low.

Carotid sinus massage

Carotid sinus massage (Practical Box 14.3) may lead to asystole (>3 s) and/or a fall of systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population, but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (p. 676). In one-third of cases, carotid sinus massage is only positive when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid

Figure 14.22 Tilt test. The ECG (top trace) and arterial blood pressure (bottom trace) recorded during a tilt test. After 1 min of tilt, hypotension, bradycardia and syncope occur.

arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely used in clinical cardiology. It involves the use

Practical Box 14.3

Carotid sinus massage

- Ensure there is no significant carotid artery disease (carotid bruits).
- Provide continuous electrocardiographic monitoring.
- Patient is in supine position with the head slightly extended.
- Start with right carotid sinus massage.
- Apply firm rotary pressure to the carotid artery at the level of the third cervical vertebra for 5 s.
- Alternatively, steady pressure can be applied.
- If no response, massage left carotid sinus.
- Generally, right carotid sinus massage decreases the sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
- Do not massage both carotid sinuses at the same time.
- Single application of carotid sinus pressure may be effective in about 20–30% of patients with paroxysmal supraventricular tachycardias; multiple applications can terminate tachycardia in about 50% of patients.
- Asystole is a potential but rare complication.

of ultrasound (either alone or with contrast agent) to assess cardiac structure and function. A physician or technician performs the studies and a comprehensive examination takes 15–45 minutes. The ultrasound machines are either mobile on wheels, or are handheld.

Physics

Echocardiography uses transmitted ultrasound wavelengths of ≤ 1 mm, which correspond to frequencies of approximately ≥ 2 MHz (≥ 2 million cycles per second). At such high frequencies, the ultrasound waves can be focused into a 'beam' and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

Echocardiographic modalities

M mode and two-dimensional echocardiography

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines, the distances of which from the top of the screen indicate their depths, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 14.23c). Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography) (Fig. 14.23a,b). This method is useful for delineating anatomical structures and for quantifying volumes of cardiac chambers. M mode can be used to estimate LV systolic function by comparing end-diastolic

Figure 14.23 Echocardiograms. (a) Diagram showing the anatomy of the area scanned and a diagrammatic representation of the echocardiogram. (b) and (c) Echocardiograms from a normal subject: (b) Two-dimensional long-axis view. (c) M-mode recording with the ultrasound beam directed across the left ventricle, just below the mitral valve. AMVC, anterior mitral valve cusp; AO, aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; LV(d), LV(s), left ventricular end-diastolic and end-systolic dimensions; MV, mitral valve; PM, papillary muscle; PMVC, posterior mitral valve cusp; PVW, posterior ventricular wall; RA, right atrium; RV, right ventricle; RVOT, right ventricular outflow tract.

and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size ('shortening fraction' – SF) is given by:

$$SF = \frac{LVDD - LVSD}{LVDD} \times 100\%$$

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30–45%.

This method is easy to perform, but is an inaccurate measure of *ejection fraction (EF)* because it does not take account of reduced regional function of the mid or apical myocardium, due to infarction for example. For this reason, estimation of EF based upon the difference in LV volumes from systole to diastole, derived from planimetric measurements of LV area in at least two planes, is more accurate. A normal EF is >55%. This method is helpful in assessing the response of the patient with heart failure to therapy. It also permits estimation of LV mass.

Three-dimensional echocardiography

Three-dimensional echocardiography is a novel development in cardiac imaging in which a volumetric dataset is acquired using a multiplane probe rotating around a fixed axis. Clinical uses include accurate volumetric assessment of ventricular function and mass, assessment of mitral and aortic valve disease and assessment of adult congenital heart disease (Fig. 14.24).

Doppler echocardiography

Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a 2-D image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume

cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts.

Cardiac output can then be derived using the formula: $CO = \text{stroke volume} \times \text{heart rate}$. Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as part of the estimation of left ventricular filling pressure.

Colour flow Doppler. Doppler colour flow imaging uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 14.25) and may be useful in the assessment of coronary blood flow.

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is used typically to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur. These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of $4 \times 5 \times 5 = 100$ mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and intraventricular obstruction (as in hypertrophic cardiomyopathy). It is often clinically unnecessary to resort to invasive methods such as

Figure 14.24 3-D Echocardiograph in a patient with an atrial septal defect (*). The mitral valve (+) and the left atrial anatomy are well delineated. (AVI available online: <http://www.asecho.org/files/3D.pdf>.)

Figure 14.25 Colour Doppler shows blood flowing away from the echocardiography probe as a blue signal and towards the probe as a red signal. In this patient with tricuspid regurgitation, blood leaks from the right ventricle to the right atrium during cardiac systole.

cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

Other ultrasound modalities. Harmonic power Doppler, pulse inversion Doppler and ultraharmonics are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

Transoesophageal echocardiography (TOE)

A transducer mounted on a flexible tube is placed into the oesophagus. This involves the use of local anaesthesia and sometimes intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used in the assessment of valve structure and function (to assess for reparability of mitral valve prolapse), for features and complications of infective endocarditis, to assess the aorta for aortic dissection and to assess for a cardiac source of embolus.

Wall motion stress echocardiography

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and of reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to sub-maximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported. This technique can also be used to assess for viability of the myocardium and for hibernating or stunned myocardium (p. 721).

Myocardial perfusion echocardiography

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes such as harmonic power Doppler can be used for detection. MPE involves the use of intravenous infusion of contrast to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the LV cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

Contrast echo for LV opacification

Intravenous contrast agents opacify the left ventricle and can define the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in previously 'difficult to image' patients.

Intravascular (coronary) ultrasound

Intravascular (coronary) ultrasound probes can be used to image proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure, e.g. to assess for adequacy of deployment of intracoronary stents.

Nuclear imaging

Nuclear imaging is used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical used and the technique of imaging. These data are particularly valuable when used in combination. All involve a significant radiation dose (p. 688).

Image type

Gamma cameras produce a planar image in which structures are superimposed as in a standard radiograph. Single-photon-emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution, but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

Myocardial perfusion and viability

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less ^{201}Tl and appear dark. Between 2 and 24 h after injection, ^{201}Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images at this time show dark areas where the myocardium has infarcted, but normal density in ischaemic areas. Comparison of the early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty. Technetium-99-labelled tetrofosmin (Fig. 14.26) is also taken up rapidly by cardiac myocytes, but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of [$^{99\text{m}}\text{Tc}$]tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (p. 721). In patients unable to exercise, the heart can be stressed with drugs, e.g. dipyridamole or dobutamine.

Infarct imaging

Perfusion images produced using compounds labelled with ^{201}Tl or [$^{99\text{m}}\text{Tc}$]sestamibi show a myocardial infarction as a perfusion defect or 'cold spot'. These methods are sensitive for detecting and localizing the infarct, but give no information about its age. [$^{99\text{m}}\text{Tc}$]Pyrophosphate is preferentially taken up by myocardium which has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

Figure 14.26 Myocardial SPECT study acquired with [^{99m}Tc]tetrofosmin tracer. Left panel: three short-axis slices, a horizontal and a vertical axis plane of the left ventricle after stress and following a resting re-injection of tracer. The rest images demonstrate normal tracer uptake (orange signal) in the whole of the left ventricle. The stress images demonstrate reduced tracer uptake (arrows; purple-blue signal) in the anterior and septal walls consistent with a significant stenosis in the left anterior descending artery. Middle panel: polar maps of the whole myocardium can localize the ischaemic territory. Right panel: quantitative analysis can help define the extent and reversibility of the ischaemia.

Cardiac computed tomography

Computed tomography is useful for the assessment of the thoracic aorta and mediastinum. The development of 64-slice multidetector CT (MDCT) scanners has enabled accurate non-invasive imaging of the coronary arteries.

Coronary artery calcification

Calcium is absent in normal coronary arteries but is present in atherosclerosis and increases with age. Studies have demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. Electron beam CT (EBT) and MDCT scanners are used to obtain multiple thin axial slices through the heart and then the calcium score is calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with higher event rate and higher relative risk ratios, although currently no study has shown a net effect on health outcomes of calcium scoring. The current NICE chest pain guidelines recommend the use of CT calcium scoring in patients with chest pain and a 10–29% likelihood of coronary artery disease (p. 730).

CT coronary angiography

CT coronary angiography (CTCA) is performed with a supine patient connected to a 3-lead ECG for cardiac synchronization. The 64-slice MDCT scanners have a temporal resolution of 165–210 ms and image quality is optimal with a slow

and steady heart rate (<65–70 b.p.m.), which can be obtained with the use of oral or intravenous beta-blockers. Sublingual nitroglycerin (0.4–0.8 mg dose) may improve visualization of the coronary artery lumen. A volume dataset containing the whole heart is acquired during a single breath-hold with the injection of 60–80 mL of iodinated contrast agent at 4–6 mL/s. The radiation dose during the scan is 11–22 mSv but this can be reduced to 7–11 mSv with ECG-controlled dose modulation; this compares with 2.5–5.0 mSv for diagnostic coronary angiography and 15–20 mSv for SPECT. The volume dataset is then analysed with multiplanar reformatting for the presence of coronary artery stenoses (Fig. 14.27). Recent studies have reported high sensitivity (>85%) and specificity (>90%) for the detection of coronary artery disease with a very high negative predictive value (>95%). CTCA may become part of an acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism and coronary artery disease. However CT coronary angiography does expose the patient to ionizing radiation.

Cardiovascular magnetic resonance

Cardiovascular magnetic resonance (CMR), a non-invasive imaging technique that does not involve harmful radiation, is increasingly used in the investigation of patients with cardiovascular disease.

CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different

a

sequences are used to provide anatomical and functional information. Most sequences do not require a contrast agent but intravenous gadolinium may be required for magnetic resonance angiography, myocardial perfusion, infarct and fibrosis imaging. The major contraindications are permanent pacemaker or defibrillator, intracerebral clips and significant claustrophobia. Patients with coronary stents and prosthetic valves can be safely scanned.

Clinical use of CMR

The current indications for CMR are summarized in Table 14.5.

Congenital heart disease

CMR provides additional and complementary information to echocardiography in patients with congenital heart disease.

Table 14.5 Cardiovascular magnetic resonance (CMR)

Indications

1. Congenital heart disease (CHD):
anatomical assessment following echocardiography, particularly in patients with complex CHD or following surgical intervention
follow-up/surveillance studies
anomalous pulmonary or systemic venous return
assessment of right or left ventricular function/dilatation
2. Cardiomyopathies/cardiac infiltration/pericardial disease
3. Disease of the aorta, including aortic dissection, aneurysm, coarctation
4. Valvular heart disease:
quantification of stenosis and regurgitation
accurate ventricular dimensions/function
planimetry of valvular stenosis
5. Coronary artery disease:
left and right ventricular function
wall motion assessment during dobutamine stress
myocardial perfusion during adenosine stress
coronary artery and coronary artery bypass graft imaging
myocardial infarct imaging and viability assessment with dobutamine CMR or delayed enhancement
6. Pulmonary vessels

Cine imaging can accurately assess systemic and non-systemic ventricular function and mass. Extracardiac conduits, anomalous pulmonary venous return and aortic coarctations pre- and post-repair can be studied by CMR and the studies repeated for long-term follow-up without the risk of ionizing radiation.

Cardiomyopathies, pericardial disease and cardiac masses

In hypertrophic cardiomyopathy CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with sub-optimal echocardiograms. Intravenous gadolinium can be used to demonstrate regional myocardial fibrosis which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy, CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract, and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava), but can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 14.28). In patients with dilated cardiomyopathy CMR can accurately quantify bi-ventricular function and with gadolinium can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis and amyloidosis, CMR is increasingly used as a diagnostic investigation due to different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia, CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.

Diseases of the aorta

CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection; the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion and aortic dilatation.

Figure 14.28 Short-axis cardiac magnetic resonance (CMR) in a patient with constrictive pericarditis. The pericardium is thickened (*) and on cine imaging (c) there is septal bounce. LV, left ventricle; RV, right ventricle.

Figure 14.29 Cardiac magnetic resonance (CMR). A diagnostic coronary angiography in a patient with type 2 diabetes mellitus and exertional breathlessness demonstrates a severe stenosis (*) in the right coronary artery (RCA), a sub-totally occluded (+) circumflex coronary artery (LCX), and a long segment of disease (X) in the left anterior descending coronary artery (LAD).

As it does not involve radiation or need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.

Valvular heart disease

Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricle which are equal in the absence of significant regurgitation. However, in most patients, transthoracic and transoesophageal echocardiography should provide sufficient information.

Coronary artery disease

CMR can be used to assess coronary artery anatomy, left ventricular function, myocardial perfusion and viability in a 'one-stop' approach to the assessment of patients with coronary artery disease. Coronary artery anatomy and stenoses can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with cine imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilatation. Myocardial viability can be determined using gadolinium and 'delayed enhancement' images. With these techniques CMR is increasingly used both for the assessment of ischaemia in

patients with suspected coronary disease and to assess myocardial viability prior to revascularization in patients with impaired cardiac function (Figs 14.29, 14.30).

Pulmonary vessels

Magnetic resonance angiography with gadolinium can provide high quality images of the pulmonary veins which can be fused with electrical data during pulmonary vein isolation for the treatment of atrial fibrillation.

Positron emission tomography (PET)

This is a technique based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. There are several advantages of PET over other techniques, e.g. improved spatial resolution, accurate quantification, the use of biological isotopes of carbon, nitrogen and oxygen. However, PET is expensive and requires a cyclotron to produce the short-lived tracers. PET has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with ^{13}N -ammonia or oxygen-15 with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of ^{18}F -fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating

Figure 14.30 Cardiac magnetic resonance (CMR). (a) Short-axis CMR FIESTA cine imaging (diastole top, systole bottom) demonstrates thinning and hypokinesia of the inferolateral wall (arrows) but with preserved function of the rest of the myocardium. LV, left ventricle; RV, right ventricle. (b) First-pass perfusion CMR (mid top, apex bottom) demonstrates subendocardial perfusion defects in the inferolateral wall (+), infero-septum (*) and apical segments (X). (c) Delayed enhancement CMR confirms a transmural myocardial infarction of the mid-apical infero-lateral wall (+) secondary to a previous infarction from the circumflex coronary artery and confirms inducible ischaemia in the right and left coronary territories.

myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake.

Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers, and pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by 'wedging' a catheter into the distal pulmonary artery (p. 874). In this position the pressure from the right ventricle is obstructed by the catheter and only the pulmonary venous and left atrial pressures are recorded. Left heart catheterization is usually performed via the right femoral or radial artery. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material is used to opacify the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the 'pullback' gradient across the valve is measured. Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation. Specially designed catheters are then used to selectively engage the left and right coronary arteries, and contrast cine-angiograms are taken in order to define the coronary circulation and

identify the presence and severity of any coronary artery disease. During the procedure intracoronary nitrate or adenosine may be used to dilate the coronary arteries. During cardiac catheterization, blood samples may be withdrawn to measure the oxygen content. These estimations are used to quantify intracardiac shunts and measure cardiac output.

THERAPEUTIC PROCEDURES

Cardiac resuscitation

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. The **chain of survival** (Fig. 14.31) includes early recognition of cardiac arrest; early activation of emergency services; early cardiopulmonary resuscitation (CPR); early defibrillation and early advanced life support; and high quality post resuscitation care.

Basic life support (BLS)

The first step is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking him/her and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of basic life support. If the victim has absent or abnormal breathing then cardiac arrest is confirmed and basic life support should be started (Emergency Box 14.1).

Airway

Debris (e.g. blood and mucus) in the mouth and pharynx should be removed. Loose or ill-fitting dentures should be removed. The airway should be opened gently by flexing the neck and extending the head ('sniffing the morning air'

Chain of survival

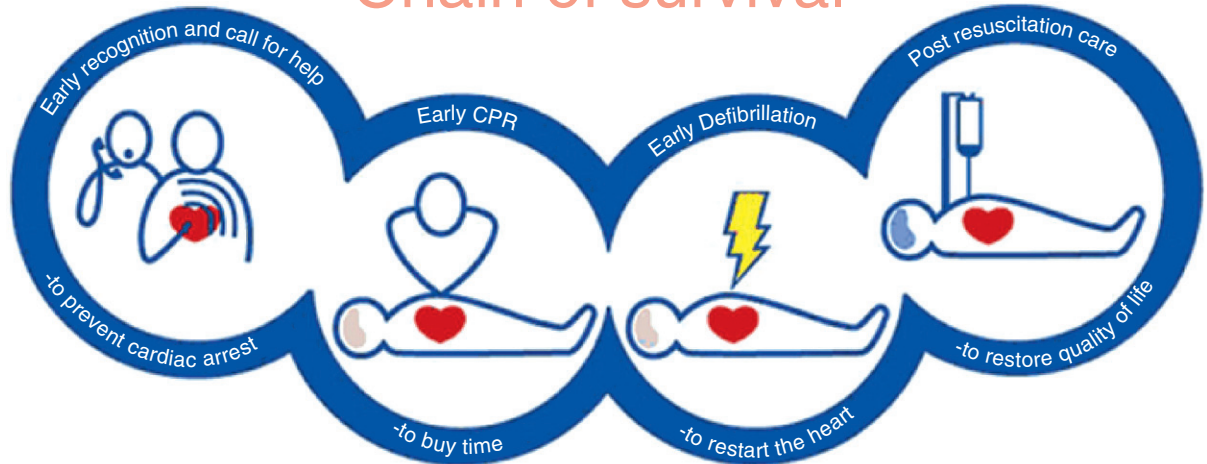

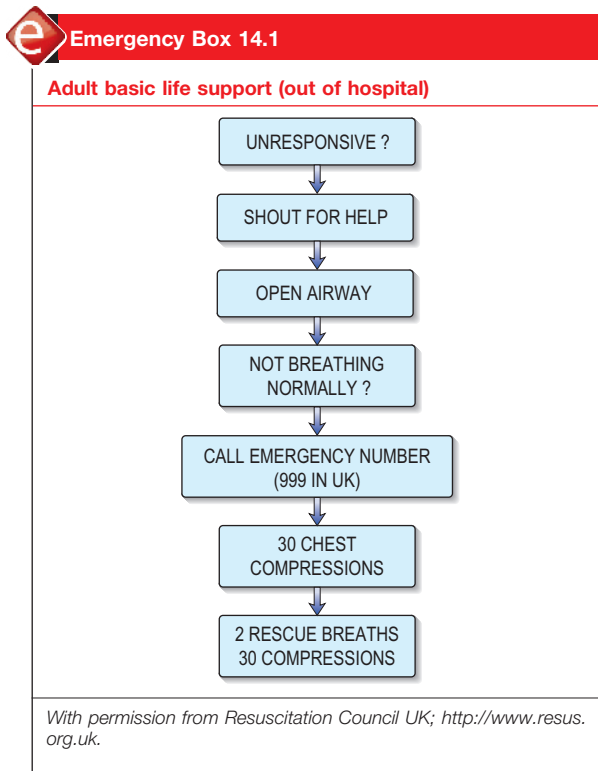

Figure 14.31 Cardiopulmonary resuscitation chain of survival.

position). This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may require abdominal and/or chest thrusts (Heimlich manoeuvre, in this chapter).

Circulation

Most adult cardiac arrest is due to a primary cardiac disorder, e.g. acute coronary syndrome, and results in circulatory collapse. Pulse detection can be difficult and if the victim is unresponsive with absent or abnormal breathing then external chest compression should be started immediately:

- The heel of one hand is placed over the centre of the chest and the heel of the second hand is placed over the first with the fingers interlocked.
- The arms are kept straight and the sternum is rhythmically depressed by 5–6 cm at a rate of

approximately 100–120/min allowing for complete recoil between compressions.

Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 30 cardiac compressions (30:2 for one or two persons, 15:2 in paediatric patients). Compressions alone is as good as compressions with rescue breaths (American Heart Association updated guidelines). This maintains adequate cerebral and coronary perfusion pressures. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates.

Breathing

After 30 compressions the rescuer opens the victim's airway by tilting the head backwards (*head tilt*) and pulling the chin pulled forward (*chin lift*) or (*jaw thrust*). The rescuer then pinches the nostrils firmly and takes a deep breath and seals his/her lips around the mouth of the victim. Two effective breaths are given over 1 s each. In paediatric patients respiratory arrests are more common and patients should be given five rescue breaths and a minute of CPR before a sole rescuer leaves the victim to seek help. CPR should not be interrupted to reassess the victim unless they start to show signs of life and start to breathe normally.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support can begin. This consists of ECG monitoring, advanced airway management (endotracheal intubation or supraglottic airway tube) and setting up an intravenous infusion in a large peripheral or central vein (an intraosseous needle may be used if i.v. access is not possible). As soon as possible the cardiac rhythm should be established as this determines which pathway of the European Resuscitation Council and the Resuscitation Council UK ACLS Algorithm is followed (Fig. 14.32). This can be determined with an automated external defibrillator (AED), or the paddles or limb leads of a standard defibrillator.

If the ECG shows a shockable rhythm – ventricular fibrillation or pulseless ventricular tachycardia then an unsynchronized shock of 150–200 J biphasic (360 J monophasic) is delivered without delay via paddles or self-adhesive pads followed immediately by 2 minutes of CPR. For a non-shockable rhythm – asystole or pulseless electrical activity,

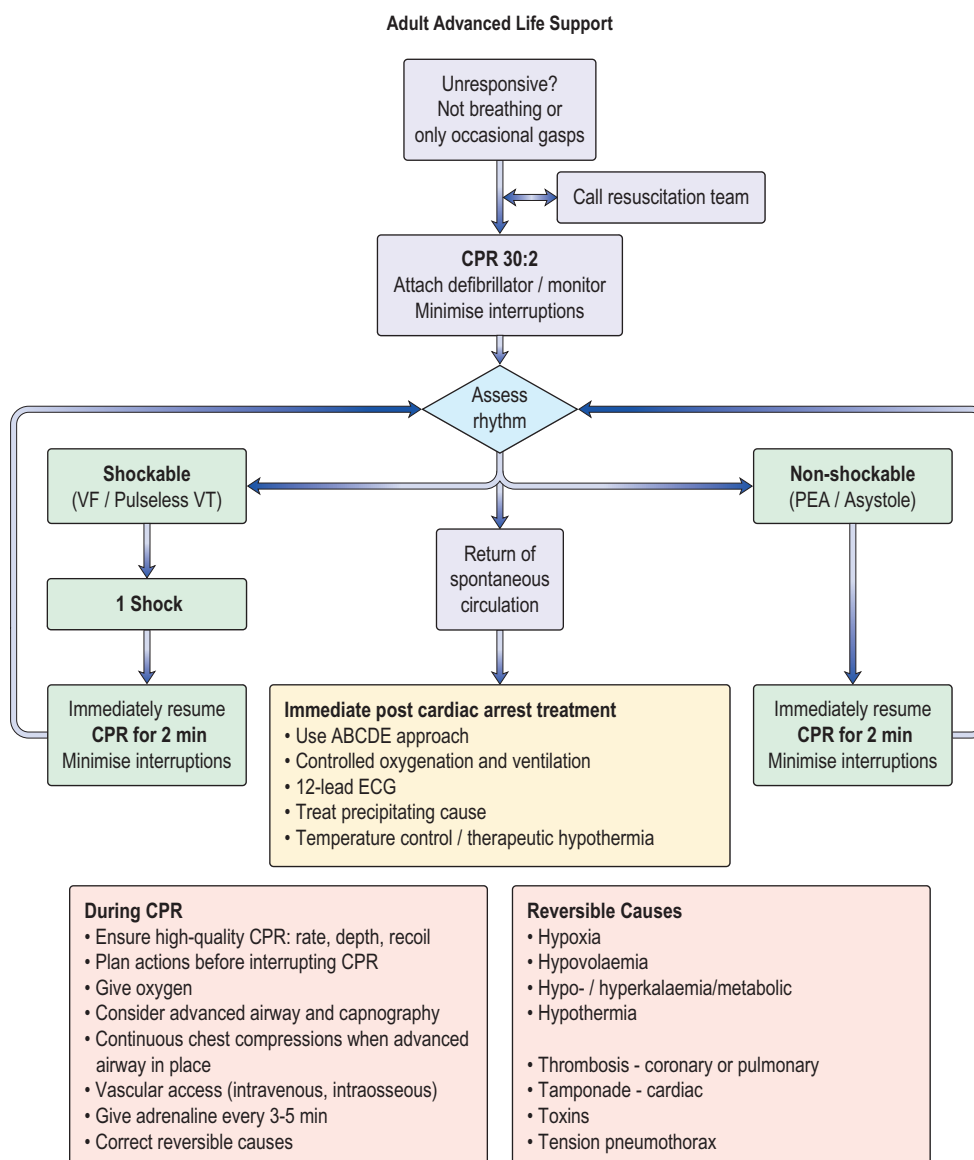

Figure 14.32 Adult advanced life support algorithm. CPR, cardiopulmonary resuscitation; PEA, pulseless electrical activity; VF, ventricular fibrillation. (Reproduced with permission from the Resuscitation Council: <http://www.resus.org.uk/pages/alsalgo.pdf>)

2 minutes of CPR is delivered with 1 mg of intravenous adrenaline (epinephrine).

For both sides of the algorithm, it is necessary to maintain CPR, ensure oxygenation, and to exclude/treat reversible causes – the ‘4 Hs and 4Ts’:

- **Hypoxia** should be minimized by ventilating the patient with oxygen and a bag-valve mask or advanced airway (endotracheal intubation or supraglottic airway tube) insuring that there is bilateral air entry and chest expansion. With an advanced airway CPR should continue with a ventilation rate of 10/minute without interrupting cardiac massage.
- **Hypovolaemia** is a frequent cardiac of pulseless electrical activity due to haemorrhage. Intravenous volume should be replaced.
- **Hyper- or hypokalaemia** may cause ECG abnormalities and should be detected by biochemical testing. Intravenous calcium chloride may be helpful in hyperkalaemia or hypocalcaemia. Acidosis should be managed with effective ventilation.
- **Hypothermia** should be excluded with a low reading thermometer and treated with external or internal warming.
- **Tension pneumothorax** may occur during central venous cannulation or following chest trauma. Clinical diagnosis (deviated trachea, hyperresonant chest, absent breath-sounds, ultrasound) and needle thoracocentesis/thoracostomy may be required.
- **Tamponade** should be excluded with echocardiography and if present treated with pericardiocentesis.
- **Toxins** may have been ingested by accident or deliberate self-harm and specific antidotes should be considered in appropriate patients.
- **Thromboembolism** and massive pulmonary embolism may cause pulseless electrical activity and patients should be considered for intravenous thrombolysis.

Causes of unexpected cardiac arrest

Each year in the UK, there are approximately 100 000 unexpected deaths occurring within 24 hours of the development

Table 14.6 Causes of unexpected cardiac arrest

Cardiac arrhythmias (e.g. ventricular fibrillation)
Sudden pump failure (e.g. acute myocardial infarction)
Acute circulatory obstruction (e.g. pulmonary embolism)
Cardiovascular rupture (e.g. aortic dissection, myocardial rupture)
Vasomotor collapse (e.g. in pulmonary hypertension)

UK sign indicating location of automated external defibrillators
(UK Resuscitation Council).

Nolan JP, Soar J, Zideman DA et al; ERC Guidelines Writing Group. European Resuscitation Council Guidelines for Resuscitation 2010, Section 1. Executive summary. *Resuscitation* 2010; 81(10):1219–1276.

of cardiac symptoms. About half of these deaths are almost instantaneous. There are several causes (Table 14.6).

Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia, and a small proportion are due to severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in western society. Transient ischaemia is suspected as the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

There are two mechanisms of sudden unexpected cardiac arrest:

- Ventricular fibrillation or pulseless ventricular tachycardia (VF/VT)
- Non-VF/VT (asystole and pulseless electrical activity also known as electromechanical dissociation).

The principal difference in the management of these two groups of arrhythmias is the need for attempted defibrillation in those patients with VF/VT (Fig. 14.32).

Three-quarters of arrests are due to ventricular fibrillation or rapid ventricular tachycardia. Only a very small proportion is due to pulseless electrical activity. The remainder is due to asystole. An agonal rhythm is characterized by an inexorable slowing and widening of the QRS complexes associated with falling blood pressure and cardiac output. This type of arrhythmia is very difficult to reverse and usually no attempt should be made because it is the result rather than the cause of death.

Arrests are treated in the following ways:

- Ventricular fibrillation or pulseless ventricular tachycardia is readily treated with **IMMEDIATE** defibrillation, cardiopulmonary resuscitation (CPR) and drugs. Intravenous amiodarone is the first-line drug in refractory VF/pulseless VT. When treating VF/VT cardiac arrest, adrenaline 1 mg is given after the third shock and then every 3–5 min. Amiodarone 300 mg is also given after the third shock, particularly if VT/VF have recurred after defibrillation.
- Asystole is more difficult to treat but the heart may respond to atropine. However atropine is not longer recommended for routine use. More recently, vasopressin has been shown to be successful. If there is any sign of slow electromechanical activity (e.g. bradycardia with a weak pulse), emergency pacing should be used. Continued CPR is critical and drug management is rarely effective.
- Pulseless electrical activity: several potentially reversible causes are listed in the universal algorithm (Fig. 14.32). It carries a very poor prognosis. Effective treatment involves continued CPR and addressing the underlying cause.

Defibrillation

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelopes the heart which depolarizes the myocardium and allows an organized heart rhythm to emerge.

Electrical energy is discharged through two paddles with gel pads or adhesive pads placed on the chest wall.

The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other is placed over the anterior wall of the left chest.

All personnel should stand clear of the patient. The person performing defibrillation has the responsibility for ensuring the safety of the patient and other people present. Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators which require less energy are increasingly common. Automated external defibrillators (AEDs) which recognize ventricular fibrillation automatically deliver a shock if indicated. These are available in some public places (in the UK their location is noted by a specific sign as shown). It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace. Provision of AEDs in residential areas or in the homes of patients at risk has not proved an effective therapy.

Post resuscitation – therapeutic hypothermia

Randomized studies have supported the use of therapeutic hypothermia in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. These patients should be cooled with careful temperature monitoring to 32–34°C for 12–24 h. External cooling methods include the use of cooling blankets; ice packs to the groin, axillae and neck; wet towels; and a cooling helmet. Invasive methods include intravenous infusions and peritoneal and pleural lavage. Shivering should be prevented by the use of a neuromuscular blocker and sedation to reduce oxygen consumption. Neurological recovery is more favourable in patients with purposeful movements and EEG activity within 3 days of a cardiac arrest.

DC cardioversion (DCC)

Tachyarrhythmias that do not respond to medical treatment or that are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic or powerful sedation is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, the delivery of the shock should be timed to occur with the downstroke of the QRS complex (synchronization) (Fig. 14.33). The machine being used to perform the cardioversion will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

- Atrial fibrillation
- Atrial flutter
- Sustained ventricular tachycardia
- Junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for >48 hours, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. Alternatively, cardioversion may be performed if intra-atrial thrombus is ruled out using a transoesophageal

Figure 14.33 DC-cardioversion of a supraventricular tachycardia to sinus rhythm. The direct current shock is delivered synchronously with the QRS complex.

echocardiogram. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be for at least 4 weeks after the procedure and should be indefinite if risk factors for stroke exist.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary pacing

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or atrioventricular block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities in whom the risk of progression to symptomatic bradycardia justifies such a strategy.

Transvenous pacing is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 14.34a) is almost always set to work 'on demand' – to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80/minute.

Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities and may be life-saving for patients in whom a cardiac arrest is precipitated by bradycardia. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient. However, it can usually be tolerated until a temporary transvenous pacemaker is inserted.

Permanent pacing

Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (Fig. 14.34b). The pacemaker is powered by solid-state lithium batteries, which usually last 5–10 years. Pacemakers are 'programmable' in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that

a

b

c

Figure 14.34 Pacemakers. (a) A temporary pacemaker unit. (b) A permanent pacemaker with atrial (placed in the right atrium, usually in its high lateral wall) and ventricular (placed in the right ventricular apex) leads. (c) An electrocardiogram showing dual (atrial and ventricular) chamber pacing. A wide QRS complex results from abnormal activation of the ventricles from the right ventricular apex.

transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers.

Pacemakers are designed to both pace and sense either the ventricles or the atria or more commonly both chambers. A single chamber ventricular pacemaker is described as a 'VVI' unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle ('dual chamber' pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D) and reacts in two (D) ways – pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (Fig. 14.34c).

In addition, pacemakers may be 'rate responsive' (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration, or changes in QT interval, and by employing one or more biosensors, changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony, whereas inactive or infirm patients may not benefit from the most sophisticated units. Specialized biventricular pacemakers are used for the treatment of severe heart failure.

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic or subclavian veins. Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously in front of the pectoral muscle. Following surgery, which usually takes 60–90 minutes, the patient rests in bed for 6–12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:

- Infection
- Erosion
- Pocket haematoma
- Lead displacement
- Electromagnetic interference.

Pericardiocentesis

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed to relieve symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting. In an emergency it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical

analysis, microscopy, including cytology, Gram-stain and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

Right-heart bedside catheterization

Bedside catheterization (Fig. 16.18) of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swann-Ganz catheter) is performed in patients with:

- Cardiac failure
- Cardiogenic shock
- Doubtful fluid status.

Intra-aortic balloon pumping

This is a technique used to assist temporarily the failing left ventricle. A catheter with a long sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the aortic arch (Fig. 14.35). The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and consequently to improve coronary and cerebral blood flow. During systole the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Intra-aortic balloon pumping is used for circulatory support in the following acute situations:

Figure 14.35 Intra-aortic balloon pump – inflated in aorta on the left and deflated on the right.

- **Acute heart failure.** Balloon pumping is used to improve cardiac output when there is a transient or reversible depression of left ventricular function, such as in a patient with severe mitral valve regurgitation who is awaiting surgical replacement of the mitral valve, or in a patient with a ventricular septal defect that is due to septal infarction. It may also be used to support patients awaiting heart transplantation.
- **Unstable angina pectoris.** Balloon pumping is used to treat unstable angina pectoris by improving coronary flow and decreasing myocardial oxygen consumption by reducing the 'afterload'. This technique may be successful, even when medical therapy has failed. It is followed by early angiography and appropriate definitive therapy such as surgery or coronary angioplasty.

Balloon pumping should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease.

Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- **Bradycardia:** the heart rate is slow (<60 b.p.m. during the day or <50 b.p.m. at night)
- **Tachycardia:** the heart rate is fast (>100 b.p.m.).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into supraventricular tachycardias, which arise from the atrium or the atrioventricular junction, and ventricular tachycardias, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts, and in others arrhythmias originate from diseased tissue, such as scar, as a result of underlying

structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

Sinus node function

The normal cardiac pacemaker is the sinus node (p. 669) and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone and decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I, and II of the ECG (Fig. 14.18), but inverted in the cavity leads AVR and V₁ (Fig. 14.36a).

Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens, and on expiration the heart rate falls. This variation is normal, particularly in children and young adults. Typically sinus arrhythmia results in predictable irregularities of the pulse.

Sinus bradycardia

A sinus rate of <60 b.p.m. during the day or <50 b.p.m. at night is known as sinus bradycardia.

It is usually asymptomatic unless the rate is very slow. It is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac and are discussed below in the section entitled 'Bradycardias and heart block' (see p. 698).

Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into

Figure 14.36 (a) An ECG showing normal sinus rhythm (PR interval <0.2 s). P wave preceding each QRS complex. (b) A patient with sick sinus syndrome. This shows sinus arrest (only occasional sinus P waves) and junctional escape beats (J). P waves are inverted in the cavity leads that are shown here.

systemic or cardiac and are discussed below in the section entitled 'Supraventricular tachycardias' (p. 702).

Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Figure 14.37.

Accelerated automaticity (Fig. 14.37a)

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential. For example, sympathetic stimulation releases epinephrine (adrenaline), which enhances automaticity. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.

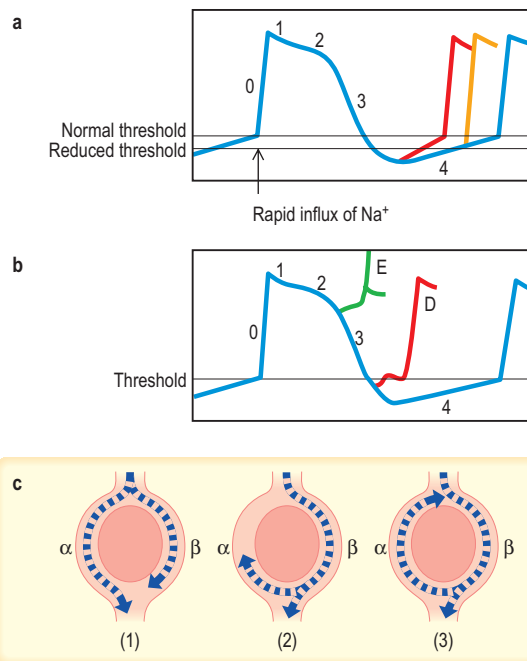

Figure 14.37 Mechanisms of arrhythmogenesis. (a,b) Action potentials (i.e. the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation. **(a)** Increased (accelerated) automaticity due to reduced threshold potential or an increased slope of phase 4 depolarization (see p. 680). **(b)** Triggered activity due to early (E) or delayed (D) 'after depolarizations' reaching threshold potential. **(c)** Mechanism of circus movement or re-entry. In panel (1) the impulse passes down both limbs of the potential tachycardia circuit. In panel (2) the impulse is blocked in one pathway (α) but proceeds slowly down pathway β , returning along pathway α until it collides with refractory tissue. In panel (3) the impulse travels so slowly along pathway β that it can return along pathway α and complete the re-entry circuit, producing a circus movement tachycardia.

Triggered activity (Fig. 14.37b)

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, which are called 'after depolarizations', may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called 'early after depolarizations' (E in Fig. 14.37b). When they develop after the transmembrane potential is completed, they are called 'delayed after depolarizations' (D in Fig. 14.37b).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, hypoxia, acidosis and some medications, which may then trigger arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (p. 708) may be caused by this mechanism.

Re-entry (or circus movements) (Fig. 14.37c)

The mechanism of re-entry occurs when a 'ring' of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block, and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

Bradycardias and heart block

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

Bradycardia

Sinus bradycardia

Sinus bradycardia is due to extrinsic factors influencing a relatively normal sinus node or due to intrinsic sinus node disease. The mechanism can be acute and reversible or chronic and degenerative. Common causes of sinus bradycardia include:

Extrinsic causes

- Hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure
- Drug therapy with beta-blockers, digitalis and other antiarrhythmic drugs
- Neurally mediated syndromes (see below).

Intrinsic causes

- Acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction)
- Chronic degenerative changes such as fibrosis of the atrium and sinus node (sick sinus syndrome).

Sick sinus syndrome or *sinoatrial disease* is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis such as ischaemic heart disease, cardiomyopathy or myocarditis can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 14.36) and commonly, owing to diffuse atrial disease, experience paroxysmal atrial tachyarrhythmias (tachy-brady syndrome).

Neurally mediated syndromes

Neurally mediated syndromes are due to a reflex (called Bezold–Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilatation. These syndromes usually present as syncope or pre-syncope (dizzy spells).

Carotid sinus syndrome occurs in the elderly and mainly results in bradycardia. Syncope occurs (see p. 676).

Neurocardiogenic (vasovagal) syncope (syndrome) usually presents in young adults but may present for the first time in elderly patients (see p. 676). It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory or mixed.

Postural orthostatic tachycardia syndrome (POTS) is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure produced by standing. The underlying mechanism is a failure of the peripheral vasculature to appropriately constrict in response to orthostatic stress, which is compensated by an excessive increase in heart rate.

Many medications, such as antihypertensives, tricyclic antidepressants and neuroleptics, can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combining two agents with potential to cause syncope help to prevent iatrogenic syncope.

Treatment

The management of sinus bradycardia is first to identify and if possible remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored and in patients with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome requires permanent pacing (DDD), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardia element. Thromboembolism is common in tachy-brady syndrome and patients should be anticoagulated unless there is a contraindication.

Patients with carotid sinus hypersensitivity (asystole >3 s), especially if symptoms are reproduced by carotid sinus massage, and in whom life-threatening causes of syncope have been excluded, benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient, and sitting/lying down and applying counter pressure manoeuvres (pushing palms together or crossing legs) if an attack threatens. Increased salt intake, compression of the lower legs with hose and drugs such as beta-blockers, alpha-agonists, e.g. midodrine, or myocardial negative inotropes (such as disopyramide) may be helpful.

In selected patients with 'malignant' neurocardiogenic syncope (syncope associated with injuries and demonstrated asystole) permanent pacemaker therapy is helpful. These patients benefit from dual chamber pacemakers with a feature called 'rate drop response' which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

Heart block

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in AV block, whereas block lower in the conduction system produces bundle branch block.

Figure 14.38 An ECG showing first-degree atrioventricular block with a prolonged PR interval. In this trace, coincidental ST depression is also present.

Atrioventricular block

There are three forms:

First-degree AV block

This is simple prolongation of the PR interval to >0.22 s. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 14.38).

Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 14.39):

- **Mobitz I block** (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- **Mobitz II block** occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually the QRS complex is wide (>0.12 s).
- **2:1 or 3:1 (advanced) block** occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor II.

Wenckebach AV block in general is due to block in the AV node, whereas Mobitz II block signifies block at an infra-nodal level such as the His bundle. The risk of progression to complete heart block is greater and the reliability of the resultant escape rhythm is less with Mobitz II block. Therefore pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

Acute myocardial infarction may produce *second-degree heart block*. In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated; 2:1 Heart block may either be due to block in the AV node or at an infra-nodal level. Management depends on the clinical setting in which it occurs.

Third-degree (complete) AV block

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 14.40). In patients with complete heart block the aetiology needs to be established (Table 14.7). In this situation life is maintained by a spontaneous escape rhythm.

Narrow complex escape rhythm (<0.12 s QRS complex) implies that it originates in the His bundle and therefore that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable.

Treatment depends on the aetiology. Recent-onset narrow-complex AV block due to transient causes may respond to intravenous atropine, but temporary pacing

Figure 14.39 Three varieties of second-degree atrioventricular (AV) block. (a) **Wenckebach (Mobitz type I) AV block.** The PR interval gradually prolongs until the P wave does not conduct to the ventricles (arrows). (b) **Mobitz type II AV block.** The P waves that do not conduct to the ventricles (arrows) are not preceded by gradual PR interval prolongation. (c) **Two P waves to each QRS complex.** The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block and it is, therefore, a third variety of second-degree AV block (arrows show P waves).

Figure 14.40 Two examples of complete heart block. (a) **Congenital complete heart block.** The QRS complex is narrow (0.08 s) and the QRS rate is relatively rapid (52 b.p.m.). (b) **Acquired complete heart block.** The QRS complex is broad (0.13 s) and the QRS rate is relatively slow (38 b.p.m.).

facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual chamber, p. 695) if it is symptomatic or associated with heart disease. Pacing is also advocated for isolated, congenital AV block, even if asymptomatic.

Broad complex escape rhythm (>0.12 s) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His-Purkinje system.

The resulting rhythm is slow (15–40 b.p.m.) and relatively unreliable. Dizziness and blackouts (*Stokes–Adams attacks*) often occur. In the elderly, it is usually caused by degenerative fibrosis and calcification of the distal conduction system (*Lev's disease*). In younger individuals, a proximal progressive cardiac conduction disease due to the inflammatory process is known as *Lenegre's disease*. Sodium channel abnormalities have been identified in both syndromes. Broad-complex

AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Permanent pacemaker implantation (p. 695) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter-defibrillator (ICD) may be indicated in those with severe left ventricular dysfunction (>0.30 s).

Bundle branch block

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.

Bundle branch conduction delay

This produces slight widening of the QRS complex (up to 0.11 s). It is known as incomplete bundle branch block.

Table 14.7 Aetiology of complete heart block

Congenital	Cardiac surgery
Autoimmune (e.g. maternal SLE)	e.g. following aortic valve replacement, CABG, VSD repair
Structural heart disease (e.g. transposition of the great vessels)	Iatrogenic
Idiopathic fibrosis	Radiofrequency AV node ablation and pacemaker implantation
Lev's disease (progressive fibrosis of distal His-Purkinje system in elderly patients)	Drug-induced
Lenegre's disease	e.g. digoxin, beta-blockers, non-dihydropyridine calcium-channel blockers, amiodarone
(proximal His-Purkinje fibrosis in younger patients)	Infections
Ischaemic heart disease	Endocarditis
Acute myocardial infarct	Lyme disease
Ischaemic cardiomyopathy	Chagas' disease
Non-ischaemic heart disease	Rheumatic autoimmune disease
Calcific aortic stenosis	e.g. SLE, rheumatoid arthritis
Idiopathic dilated cardiomyopathy	Neuromuscular diseases
Infiltrations (e.g. amyloidosis, sarcoidosis, neoplasia)	e.g. Duchenne muscular dystrophy

SLE, systemic lupus erythematosus; CABG, coronary artery bypass graft surgery; VSD, ventricular septal defect; AV, atrioventricular.

Complete block of a bundle branch

This is associated with a wider QRS complex (≥ 0.12 s). The shape of the QRS depends on whether the right or the left bundle is blocked.

Right bundle branch block (Fig. 14.41a) produces late activation of the right ventricle. This is seen as deep S waves in leads I and V_6 and as a tall late R wave in lead V_1 (late activation moving towards right- and away from left-sided leads).

Left bundle branch block (Fig. 14.42) produces the opposite – a deep S wave in lead V_1 and a tall late R wave in leads I and V_6 . Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.

Hemiblock

Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftwards movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

Bifascicular block

 (Fig. 14.41b)

This is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

Clinical features of heart blocks

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or

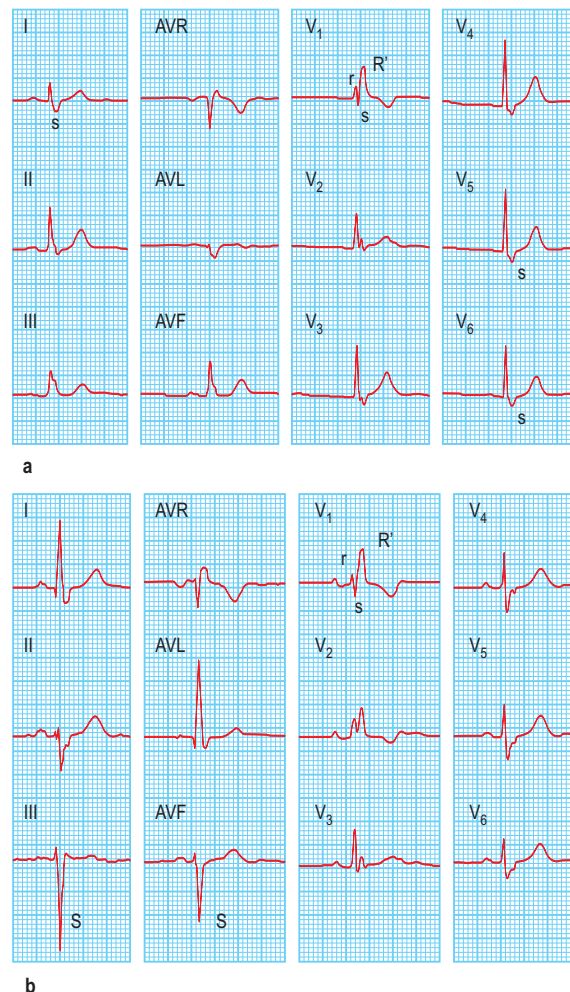

Figure 14.41 Right bundle branch block versus bifascicular block. (a) A 12-lead ECG showing right bundle branch block. Note an rsR' pattern with the tall R' in lead V_1 – V_2 and the broad S waves in leads I and V_5 – V_6 . **(b)** Compare with an ECG showing bifascicular block. In addition to right bundle branch block, note left axis deviation and deep S waves in leads III and AVF typical for left anterior hemiblock.

Figure 14.42 A 12-lead ECG showing left bundle branch block. The QRS duration is >0.12 s. Note the broad notched R waves with ST depression in leads I, AVL and V_6 , and the broad QS waves in V_1 – V_3 .

to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.

Causes

Right bundle branch block occurs as an isolated congenital anomaly or is associated with cardiac or pulmonary conditions (Table 14.8). Right bundle branch block alone does not alter the electrical axis of the heart. Axis deviations signify right ventricular hypertrophy (RV overload) or co-existent fascicular block. The combination of right bundle branch block with left axis deviation is associated with ostium primum atrial septal defects. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes are listed in Table 14.8 and are similar to those of complete heart block.

Supraventricular tachycardias

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His–Purkinje system; therefore the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular

tachycardia is listed in Table 14.9. Some of these are discussed in more detail below.

Inappropriate sinus tachycardia

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to or out of proportion with the level of physical or emotional stress. It is found predominantly in young women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate, e.g. in hyperthyroidism (p. 937); ivabradine, an I_f (pacemaker current) blocker, may be useful when beta-blockade cannot be tolerated.

Atrioventricular junctional tachycardias

AV nodal re-entry and AV re-entry tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities (e.g. Ebstein's anomaly, atrial septal defect, Fallot's tetralogy) can co-exist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5/1000.

In these tachycardias the AV node is an essential component of the re-entry circuit.

Atrioventricular nodal re-entry tachycardia (AVNRT)

This tachycardia is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, coffee, tea and alcohol may aggravate

Table 14.8 Causes of bundle branch block

Right	Left
It is a normal finding in 1% of young adults and 5% of elderly adults	Left ventricular outflow obstruction
Congenital heart disease	Aortic stenosis
Atrial septal defect	Hypertension
Fallot's tetralogy	Coronary artery disease
Pulmonary stenosis	Acute myocardial infarction
Ventricular septal defect	Severe coronary disease (two- to three-vessel disease)
Pulmonary disease	
Pulmonary hypertension	
Pulmonary embolism	
Myocardial disease	
Myocardial infarction	
Cardiomyopathy	
Conduction system, fibrosis	
Chagas disease	

Table 14.9 Causes of supraventricular tachycardia (SVT)

Tachycardia	ECG features	Comment
Sinus tachycardia	P wave morphology similar to sinus rhythm preceding QRS	Need to determine underlying cause
AV nodal re-entry tachycardia (AVNRT)	No visible P wave, or inverted P wave immediately before or after QRS complex	Commonest cause of palpitations in patients with normal hearts
AV reciprocating tachycardia (AVRT) complexes	P wave visible between QRS and T wave	Due to an accessory pathway. If pathway conducts in both directions, ECG during sinus rhythm may be pre-excited
Atrial fibrillation	Irregularly irregular RR intervals and absence of organized atrial activity	Commonest tachycardia in patients over 65 years
Atrial flutter	Visible flutter waves at 300/min (sawtooth appearance) usually with a 2:1 AV conduction	Suspect in any patient with regular SVT at 150/min
Atrial tachycardia	Organized atrial activity with P wave morphology different from sinus rhythm preceding QRS	Usually occurs in patients with structural heart disease
Multifocal atrial tachycardia	Multiple P wave morphologies (≥ 3) and irregular RR intervals	Rare arrhythmia; most commonly associated with significant chronic lung disease
Accelerated junctional tachycardia	ECG similar to AVNRT	Rare in adults

or induce the arrhythmia. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT, there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g. an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway which has already recovered its excitability, thus initiating the most common 'slow-fast', or typical, AVNRT.

The rhythm is recognized on ECG by normal regular QRS complexes, usually at a rate of 140–240/minute (Fig. 14.43a). Sometimes the QRS complexes will show typical bundle branch block. P waves are either not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. Less commonly observed (5–10%) is tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP' interval ('fast-slow', or long RP' tachycardia).

Atrioventricular reciprocating tachycardia (AVRT)

This large circuit comprises the AV node, the His bundle, the ventricle and an abnormal connection of myocardial fibres from the ventricle back to the atrium. It is called an accessory pathway or bypass tract and results from an incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, this tachycardia is due to a macro-reentry circuit and each part of the circuit is activated sequentially. As a result atrial activation occurs after ventricular activation and the P wave is usually clearly seen between the QRS and T wave (Fig. 14.43b).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most

common accessory pathways, known as *Kent bundles*, are in the free wall or septum. In about 10% of cases multiple pathways occur. *Mahaim fibres* are atrio-fascicular or nodo-fascicular fibres entering the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore 'concealed'. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the δ wave (Fig. 14.43c). Patients with a history of palpitations and a pre-excited ECG have a syndrome known as Wolff–Parkinson–White (WPW) syndrome.

During AVRT the AV node and ventricles are activated normally (*orthodromic AVRT*), resulting usually in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway and atrial activation via retrograde conduction through the AV node (*antidromic AVRT*). This results in a broad complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is characterized by irregularly irregular broad QRS complexes (Fig. 14.43d). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15–0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

Figure 14.43 Atrioventricular junctional tachycardia. (a) Atrioventricular nodal re-entry tachycardia. The QRS complexes are narrow and the P waves cannot be seen. (b) Atrioventricular re-entry tachycardia (Wolff–Parkinson–White syndrome, WPW). The tachycardia P waves (arrows) are clearly seen after narrow QRS complexes. (c) An electrocardiogram taken in a patient with WPW syndrome during sinus rhythm. Note the short PR interval and the δ wave (arrow). (d) Atrial fibrillation in the WPW syndrome. Note tachycardia with broad QRS complexes with fast and irregular ventricular rate.

Symptoms

The leading symptom of most SVTs, in particular AV node re-entry and AV re-entry tachycardias, is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain and weakness. Polyuria may occur because of release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia, especially during AVNRT and atrial fibrillation. Prominent jugular venous pulsations due to atrial contractions against closed atrioventricular valves may be observed during AVNRT.

Syncope has been reported in 10–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the patient is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Acute management

In an emergency, distinguishing between AVNRT and AVRT may be difficult, but it is usually not critical as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (Practical Box 14.3), Valsalva manoeuvre (Practical Box 14.4) and facial immersion in cold water can be successfully employed.

Of these techniques, the Valsalva manoeuvre is the best and is often easier for the patient to perform successfully. It should be undertaken when the patient is resting in the

supine position (thus avoiding elevated background sympathetic tone). Several seconds after the release of strain, the resulting intense vagal effect may terminate AVNRT or AVRT or may produce sufficient AV block to reveal an underlying atrial tachyarrhythmia.

If physical manoeuvres have not been successful, intravenous adenosine (initially 6 mg by i.v. push, followed by 12 mg if needed) should be tried. This is a very short-acting (half-life <10 s) naturally occurring purine nucleoside that causes complete heart block for a fraction of a second following i.v. administration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity. It rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but include:

- Bronchospasm
- Flushing
- Chest pain
- Heaviness of the limbs
- Sense of impending doom.

It is contraindicated in patients with a history of asthma. In some patients, adenosine can induce atrial fibrillation.

An alternative treatment is verapamil 5–10 mg i.v. over 5–10 min, i.v. diltiazem, or beta-blockers (esmolol, propranolol, metoprolol). Verapamil (or diltiazem) must not be given after beta-blockers or if the tachycardia presents with broad (>0.12 s) QRS complexes.

Long-term management

Patients with suspected cardiac arrhythmias should always be referred to the cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological alternatives, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem and beta-blockers have proven efficacy in 60–80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide), and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate for ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

Atrial tachyarrhythmias

Atrial tachyarrhythmias including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats all arise from the atrial myocardium (Fig. 14.44). They share common aetiologies, which are listed in Table 14.10.

Atrial fibrillation

This is a common arrhythmia, occurring in 1–2% of the general population and 5–10% of patients over 75 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium, may cause atrial fibrillation. There are also many genetic and systemic causes of atrial fibrillation (Table 14.10).

Although rheumatic heart disease, alcohol intoxication and thyrotoxicosis are the 'classic' causes of atrial fibrillation, hypertension and heart failure are the most common causes.

Practical Box 14.4

Valsalva manoeuvre

- Valsalva manoeuvre is an abrupt voluntary increase in intrathoracic and intra-abdominal pressures by straining.
- Provide continuous electrocardiographic monitoring.
- Patient is in supine position.
- Patient should not take deep inspiration before straining.
- Ideally, the patient blows into the mouthpiece of a manometer against a pressure of 30–40 mmHg for 15 s.
- Alternatively, the patient strains for 15 s while breath-holding.
- Transient acceleration of tachycardia usually occurs during the strain phase as a result of sympathetic excess.
- On release of strain, the rate of tachycardia slows because of the compensatory increase in vagal tone (baroreceptor reflex), and it may be terminated in about 50% of patients.
- Termination of tachycardia may be followed by pauses and transient ventricular ectopics.

Figure 14.44 ECGs of a variety of atrial arrhythmias. **(a)** Atrial premature beats (arrows). The premature P wave is different from the sinus P wave and conducts to the ventricle with a slightly prolonged PR interval. **(b)** Atrial tachycardia with second-degree atrioventricular block. Note the fast atrial (P wave) rate of 150/min and the slower ventricular (R wave) rate of 75/min. **(c)** Atrial flutter. Some flutter waves are marked with an F. In this case the flutter frequency is 240/min. Every fourth flutter wave is transmitted to the ventricles and the ventricular rate is therefore 60/min. **(d)** Atrial fibrillation. Note absolute rhythm irregularity and baseline undulations (f waves).

Table 14.10 Causes of atrial tachyarrhythmias

Cardiac	Non-cardiac
Hypertension	Thyrotoxicosis
Congestive heart failure	Phaeochromocytoma
Coronary artery disease and myocardial infarction	Acute and chronic pulmonary disease (pneumonia, chronic obstructive pulmonary disease)
Valvular heart disease	Pulmonary vascular disease (pulmonary embolism)
Cardiomyopathy: dilated, hypertrophic	Electrolyte disturbances (hypokalaemia)
Myocarditis and pericarditis	Increased sympathetic tone (exercise, adrenergically mediated arrhythmia)
Wolff–Parkinson–White syndrome	Increased parasympathetic tone (vagally induced and postprandial arrhythmia)
Sick sinus syndrome	Alcohol misuse ('holiday heart' and long-term use)
Cardiac tumours	Caffeine, smoking, recreational drug use, e.g. cannabis
Cardiac surgery	Myotonic dystrophy type 1
Familial tachyarrhythmia (e.g. lone atrial fibrillation)	Chagas' disease
Genetic predisposition	

Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with unaccounted atrial fibrillation. Atrial fibrillation occurs in one-third of patients after cardiac surgery. It usually manifests during the first 4 days and is associated with increased morbidity and mortality, largely due to stroke and circulatory failure, a longer hospital stay, and later recurrences.

In some patients no cause can be found, and this group is labelled as 'lone' atrial fibrillation. The pathogenesis of 'lone', or 'idiopathic', atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. About 30–40% of those with AF, especially those who present at a young age, have at least one parent with AF and genes associated with the sodium channel, the potassium channel, gap junction proteins and right left isomerism) have been

implicated. Gene defects linked to chromosomes 10, 6, 5 and 4 have been associated with familial AF.

Atrial fibrillation is maintained by continuous, rapid (300–600/min) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

Symptoms and signs

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, whilst others attend hospital as an emergency with rapid palpitations dyspnoea and/or chest pain following the onset of atrial fibrillation. Most patients with ongoing atrial fibrillation experience some deterioration of exercise capacity or wellbeing, but this may only be appreciated once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has a very irregular pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves. The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120–180/minute, but it slows with treatment.

The clinical classification of atrial fibrillation includes first detected, paroxysmal (stops spontaneously within 7 days), persistent (requires cardioversion to stop), and permanent (no spontaneous or induced cardioversion) forms of the arrhythmia and is helpful for the decision-making between rhythm restoration and rate control. Atrial fibrillation may be asymptomatic and the 'first detected episode' should not be regarded as necessarily the true onset.

Management

When atrial fibrillation is due to an acute precipitating event such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of AF are:

- **Ventricular rate control:** this is achieved by drugs which block the AV node (see below)
- **Cardioversion** (\pm anticoagulation): this is achieved electrically by DC shock (p. 694) or medically either by intravenous infusion of an antiarrhythmic drug such as flecainide, propafenone, vernakalant or amiodarone or by taking an oral agent (flecainide or propafenone) previously tested in hospital and found to be safe in a particular patient ('pill-in-pocket' approach).

The choice depends upon:

- how well the arrhythmia is tolerated (is cardioversion urgent?)
- whether anticoagulation is required before considering elective cardioversion
- whether spontaneous cardioversion is likely (previous history? reversible cause?).

Conversion to sinus rhythm can be achieved by electrical DC cardioversion (p. 694) in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are now standard. To minimize the risk of thromboembolism associated with cardioversion patients are fully anticoagulated with warfarin (INR 2.0–3.0) or with dabigatran 150 mg twice daily for 3 weeks before cardioversion (unless atrial fibrillation is of <48 hours duration) and at least 4 weeks after the procedure. The patient is then assessed for the necessity for long-term anticoagulation. If cardioversion is urgent, transoesophageal echocardiography may be used to document the presence or absence of atrial thrombus as a guide to possibly avoiding pre-cardioversion anticoagulation.

Long-term management of atrial fibrillation

Two strategies are available:

- 'Rate control' (AV nodal slowing agents *plus oral anticoagulation*)
- 'Rhythm control' (antiarrhythmic drugs *plus DC cardioversion plus oral anticoagulation*).

Major randomized studies in patients predominantly over the age of 65 years (AFFIRM) or in patients with heart failure (AF-CHF) have shown that there is no net mortality or symptom benefit to be gained from one strategy compared with the other. Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm and the safety/tolerability of antiarrhythmic drugs in a particular patient.

Rhythm control

This is advocated for younger, symptomatic and physically active patients. *Recurrent paroxysms* may be prevented by oral medication. In general, patients with no significant heart disease can be treated with any class Ia, 1c or III antiarrhythmic drug, although it is recommended that amiodarone (because of its substantial extracardiac adverse effect profile) should be reserved until other drugs have failed. For patients with *heart failure or left ventricular hypertrophy* only amiodarone is recommended. Patients with *coronary artery disease* may be treated with sotalol or amiodarone. Patients with *paroxysmal atrial fibrillation* or with *early persistent atrial fibrillation* (little left atrial dilatation) may be treated with left atrial

ablation. The ectopic triggers for atrial fibrillation are generally found in the pulmonary veins which can be isolated from the atria using radiofrequency or cryothermal energy. Occasionally, more extensive ablation within the left atrium is needed. These techniques are more successful than antiarrhythmic drugs and may represent a 'cure' in some patients. However, the procedure is invasive and carries some hazard of serious complications such as stroke, and bleeding in about 2% of cases. In the long term, recurrence is not uncommon and an apparently successful ablation does not remove the obligation for appropriate anticoagulation. Ablation has not been shown to improve long-term cardiovascular outcome but it does successfully treat symptoms due to atrial fibrillation.

Rate control

As a primary strategy this is appropriate in patients who:

- have the permanent form of the arrhythmia associated with symptoms which can be further improved by slowing heart rate or are older than 65 years with recurrent atrial tachyarrhythmias ('accepted' atrial fibrillation)
- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved by a combination of *digoxin*, *beta-blockers* or *nondihydropyridine calcium-channel blockers* (*verapamil* or *diltiazem*). Digoxin monotherapy may be sufficient for elderly non-ambulant patients. In younger patients the effect of catecholamines easily overwhelms the vagotonic effect of digoxin and additional AV nodal slowing agents are needed. The ventricular rate response is generally considered controlled if the resting heart rate is <110 b.p.m. but a more strict control between 60 and 80 b.p.m. at rest and <110 b.p.m. during moderate exercise may be needed if symptoms persist. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in younger individuals. Older patients with poor rate control despite optimal medical therapy should be considered for AV node ablation and pacemaker implantation ('*ablate and pace*' strategy). These patients usually experience a marked symptomatic improvement but because of the ongoing risk of thromboembolism require life-long anticoagulation.

Anticoagulation

This is indicated in patients with atrial fibrillation related to rheumatic mitral stenosis or in the presence of a mechanical prosthetic heart valve. A scoring system known as CHADS₂ is used as the first step to determine the need for anticoagulation. CHADS₂ is an acronym standing for Congestive heart failure, Hypertension, Age ≥ 75 , Diabetes mellitus and previous Stroke or TIA. Each factor scores 1 except previous stroke or TIA which scores 2. A total score of 2 implies that oral anticoagulation is needed. When the score is <2 the CHADS₂VASc scoring system should be applied. CHADS₂VASc adds Vascular disease (aorta, coronary or peripheral arteries), Age 65–74, and female Sex category. Each factor scores 1 except previous Age >75 and stroke or TIA which score 2. A CHADS₂VASc score of 2 requires oral anticoagulation and a score of 1 merits consideration for oral anticoagulation or aspirin. A score of 0 should not require any antithrombotic prophylaxis.

When oral anticoagulation is required either warfarin (dose adjusted to maintain an INR between 2.0 and 3.0) or dabigatran 150 mg two times daily (or 110 mg two times daily in elderly patients (>75 years), those with moderate renal impairment (creatinine clearance: 30 to 50 mL/min) or those taking P-glycoprotein inhibitors such as amiodarone and verapamil) can be considered. Other new oral anticoagulants, such as apixaban and rivaroxaban, are now also being used.

Atrial flutter

Atrial flutter is often associated with atrial fibrillation and often requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counter-clockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (Fig. 14.44c). In typical counter-clockwise atrial flutter, the F waves are negative in the inferior leads and positive in leads V₁ and V₂. In clockwise atrial flutter, the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth trying to reveal them by slowing AV conduction by carotid sinus massage or by the administration of AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management

Treatment of a symptomatic acute paroxysm is electrical *cardioversion*. Patients who have been in atrial flutter more than 1–2 days should be treated in a similar manner to patients with atrial fibrillation and *anticoagulated* for 3 weeks prior to cardioversion.

Recurrent paroxysms may be prevented by *class III* antiarrhythmic agents. *AV nodal blocking agents* may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is catheter *ablation* (p. 712), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure, although the later occurrence of atrial fibrillation is not uncommon.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be <1% in patients with arrhythmias. It is usually associated with structural heart disease but in many cases it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital heart disease. Atrial tachycardia with block is often a result of digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial reentry. Atrial re-entry tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by

atrial premature beats. The P'P' intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia ('warm-up') and progressive decrease prior to termination ('cool-down'). Atrial tachycardia is typically caused by a focus which is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

Figure 14.44b demonstrates an atrial tachycardia at an atrial rate of 150/minute. The P waves are abnormally shaped and occur in front of the QRS complexes. Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Treatment options include *cardioversion*, *antiarrhythmic drug therapy* to maintain sinus rhythm, *AV nodal slowing agents* to control rate and, in selected cases, radiofrequency catheter *ablation*.

Atrial ectopic beats

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heart beat. On the ECG they appear as early and abnormal P waves, and are usually, but not always, followed by normal QRS complexes (Fig. 14.44a). Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when *beta-blockers* may be effective.

Ventricular tachyarrhythmias

Ventricular tachyarrhythmias can be discussed under the following headings:

- Life-threatening ventricular tachyarrhythmias
- Torsades de pointes
- Normal heart ventricular tachycardia
- Non-sustained ventricular tachycardia
- Ventricular premature beats.

Life-threatening ventricular tachyarrhythmias

Sustained ventricular tachycardia and ventricular fibrillation with haemodynamic instability (e.g. syncope, hypotension) are life-threatening ventricular tachyarrhythmias.

Sustained ventricular tachycardia

Sustained ventricular tachycardia (>30 s) often results in *pre-syncope* (dizziness), *syncope*, *hypotension* and *cardiac arrest*, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually, there are clinical signs of atrio-ventricular dissociation (i.e. intermittent cannon 'a' waves in the neck) and variable intensity of the first heart sound).

The ECG shows a rapid ventricular rhythm with broad (often ≥0.14 s), abnormal QRS complexes. AV dissociation may result in visible P waves which appear to march through the tachycardia, capture beats (intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

Table 14.11 ECG distinction between supraventricular tachycardia (SVT) with bundle branch block and ventricular tachycardia (VT)

VT is more likely than SVT with bundle branch block where there is:

- a very broad QRS (>0.14 s)
- atrioventricular dissociation
- a bifid, upright QRS with a taller first peak in V_1
- a deep S wave in V_6
- a concordant (same polarity) QRS direction in all chest leads (V_1 – V_6)

Figure 14.45 Ventricular fibrillation. Four beats of sinus rhythm followed by a ventricular ectopic beat that initiates ventricular fibrillation. The ST segment during sinus rhythm is elevated owing to acute myocardial infarction in this case.

Supraventricular tachycardia with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad complex tachycardia is due to SVT with either right or left bundle branch block, then the QRS morphology should resemble a typical RBBB or LBBB pattern (Figs 14.41a, 14.42). Other ECG criteria to differentiate VT from SVT with aberrancy are indicated in Table 14.11. Some 80% of all broad complex tachycardias are due to ventricular tachycardia, and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g. hypotensive or pulmonary oedema), emergency DC cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with class I drugs or amiodarone is usually used. First-line drug treatment consists of lidocaine (50–100 mg i.v. over 5 minutes) followed by a lidocaine infusion (2–4 mg i.v. per minute). Amiodarone is given as a dilute intravenous infusion (5 mg/kg over 1 hour (loading dose)) followed by a maintenance infusion of 1200 mg over 24 hours. DC cardioversion is necessary if medical therapy is unsuccessful.

Ventricular fibrillation

This is very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious, and respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (Fig. 14.45). It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (p. 691).

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the

Figure 14.46 The Brugada ECG. ST elevation in V_1 – V_3 with right bundle branch block.

long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter-defibrillators (ICDs) are first-line therapy in the management of these patients (p. 713).

The Brugada syndrome

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South-east Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline): right bundle branch block with coved ST elevation in leads V_1 – V_3 (Fig. 14.46). Atrial fibrillation may occur.

In 20% of cases it is a monogenic inheritable condition associated with loss of sodium channel function due to a mutation in the *SCN5A* gene. Recently other mutations in the *SCN1B* gene, glycerol-3-phosphate dehydrogenase-1-like gene (*GPD1LL*-type) and genes related to calcium channel subunits *CACNA1C* and *CACNB2* have also been implicated in the genesis of this syndrome. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful in this syndrome.

Long QT syndrome

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in Table 14.12.

Congenital long QT syndrome

Two major syndromes have been described, which may (Jervell and Lange-Nielsen syndrome) or may not (Romano-Ward syndrome) be associated with congenital deafness.

Table 14.12 Causes of long QT syndrome

Congenital	Acquired
Jervell–Lange–Nielsen (autosomal recessive)	Electrolyte abnormalities
Romano–Ward (autosomal dominant)	Hypokalaemia
	Hypomagnesaemia
	Hypocalcaemia
	Drugs
	Quinidine, disopyramide
	Sotalol, amiodarone
	Tricyclic antidepressants, e.g. amitriptyline
	Phenothiazine drugs, e.g. chlorpromazine
	Antipsychotics, e.g. haloperidol, olanzapine
	Macrolides, e.g. erythromycin
	Quinolones, e.g. ciprofloxacin
	Methadone
	Poisons
	Organophosphate insecticides
	Miscellaneous
	Bradycardia
	Mitral valve prolapse
	Acute myocardial infarction
	Diabetes
	Prolonged fasting and liquid protein diets (long-term)
	Central nervous system diseases, e.g. dystrophia myotonica

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium channel genes (Table 14.13). The different genes involved appear to correlate with different phenotypes (Fig. 14.47b) that can exhibit such variable penetrance that carriers may have completely normal ECGs. There are three major subtypes: LQT1 in which the arrhythmia is usually provoked by exercise, particularly swimming; LQT2 with provocation associated with emotion and acoustic stimuli; and LQT3 where the arrhythmias occur during rest or when asleep. It is likely that identification of the mutation involved will not only improve diagnostic accuracy, particularly with cascade screening in affected families, but also guide future therapy for the congenital long QT syndrome.

Table 14.13 Single gene mutations responsible for congenital long QT syndrome

Subtype	Chromosome	Gene	Channel
LQT1	11p15.5	KCNQ1	I_{Ks} α subunit
LQT2	7q35–36	KCNH2	I_{Kr} α subunit
LQT3	3p21–24	SCN5A	I_{Na} α subunit
LQT4	4q24–27	ANK2	Na, K, Ca
LQT5	21q22.1	KCNE1	I_{Ks} α subunit
LQT6	21q22.1	KCNE2	I_{Kr} α subunit
LQT7	17q23	KCNJ2	I_{Ks} α subunit
LQT8	12p13.3	CACNA1C	I_{Ca} α subunit
LQT9	3p25.3	CAV3	
LQT10	11q23.3	SCN4B	

Figure 14.47 Prolonged QT. (a) An ECG demonstrating a supraventricular rhythm with a long QT (LQT) interval giving way to atypical ventricular tachycardia (torsades de pointes). The tachycardia is short-lived and is followed by a brief period of idioventricular rhythm. (b) Further three examples of a prolonged QT interval corresponding to three different types of LQT.

Acquired long QT syndrome

QT prolongation and torsades de pointes are usually provoked by bradycardia.

Clinical features

Patients with a long QT develop syncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). They usually terminate spontaneously but may degenerate to ventricular fibrillation, resulting in sudden death.

Torsades de pointes is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (Fig. 14.47a).

Between spells of tachycardia or immediately preceding the onset of tachycardia the ECG shows a prolonged QT interval; the corrected QT (Table 14.4, p. 682) is usually >0.50 s.

Management**Acute (acquired):**

- Any electrolyte disturbance is corrected
- Causative drugs are stopped
- The heart rate is maintained with atrial or ventricular pacing
- Magnesium sulphate 8 mmol (Mg^{2+}) over 10–15 min for acquired long QT
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

Long-term, congenital long QT syndrome is generally treated by beta-blockade, pacemaker therapy and occasionally left cardiac sympathetic denervation. LQT1 patients seem to respond well to beta-blockade and LQT3 patients are better treated with sodium channel blockers. All LQT patients should avoid drugs known to prolong the QT interval. Patients who remain symptomatic despite conventional therapy and those with marked QT prolongation or a strong family history of sudden death usually need ICD therapy.

Short QT syndrome

Five types have been described caused by genetic abnormalities leading to faster repolarization. Ventricular

arrhythmias and sudden death may occur and an ICD is the best treatment.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic VT) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so called Galavardin's tachycardia) and if untreated may lead to cardiomyopathy.

Normal heart VT either arises from a focus in the right ventricular outflow tract or in the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in >90% cases. It is sometimes difficult to distinguish arrhythmogenic right ventricular hypertrophy (p. 770) from this seemingly benign disorder.

Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is ≥ 5 consecutive beats but lasts <30 s (Fig. 14.48d). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. NSVT is documented in up to 60–80% of patients with heart disease. There is insufficient evidence on prognosis, but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction $\leq 30\%$) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality-of-life in symptomatic individuals.

Ventricular premature beats

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed by the patient. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, 'pulsus bigeminus' may occur. If premature ventricular beats are highly symptomatic, treatment with beta-blockade may be

Figure 14.48 Varieties of ventricular ectopic activity. (a) Two ventricular ectopic beats of different morphology (multimorphological). (b) Two ventricular premature beats (VPBs) occurring one after the other (a pair or couplet of VPBs). (c) Frequently repetitive ventricular ectopic activity of a single morphology. (d) Brief run of ventricular tachycardia (non-sustained ventricular tachycardia) that follows previous ectopic activity.

Table 14.14 Long-term management of tachyarrhythmias

Tachycardia	Management aims	Management strategies
AV node re-entry tachycardia (AVNRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
AV reciprocating tachycardia (AVRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
Wolff–Parkinson–White (WPW) syndrome	Relieve symptoms Prevent sudden death (esp. if documented pre-excited atrial fibrillation)	Class Ic or class III Catheter ablation
Atrial fibrillation	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Maintenance of sinus rhythm: class Ic or class III ± cardioversion catheter ablation of ectopic focus Rate control: AV-node-slowing agents AV node ablation plus pacemaker Anticoagulation
Atrial flutter	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Atrial tachycardia	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Life-threatening ventricular tachyarrhythmias	Prevent sudden death	Implantable cardioverter-defibrillator (ICD) Beta-blockers
Congenital long QT	Prevent sudden death	Beta-blockers ± pacemaker ICD Correct bradycardia Correct electrolytes
Acquired long QT	Prevent sudden death	Avoidance of all QT-prolonging drugs
Normal heart ventricular tachycardias	Relieve symptoms	Beta-blockers, calcium channel blockers Catheter ablation
Non-sustained VT (NSVT)	Relieve symptoms Prevent sudden death in certain situations	Beta-blockers Class Ic and class III ICD in clearly defined subgroups

helpful. If the ectopics are very frequent left ventricular dysfunction may develop, and if the ectopics stem from a single focus, especially when in the right ventricle, catheter ablation can be very effective.

These premature beats (Fig. 14.48a–c) have a broad (>0.12 s) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early ‘R-on-T’ ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly in patients following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Usually simple measures such as reassurance and beta-blocker therapy are all that is required.

Long-term management of cardiac tachyarrhythmias

Options for the long-term management of cardiac tachyarrhythmias include:

- Antiarrhythmic drug therapy
- Ablation therapy
- Device therapy.

To determine the optimal strategy for a given patient the following questions must be addressed:

- Is the principal aim of treatment symptom relief or prevention of sudden death?
- Is maintaining sinus rhythm or controlling ventricular rates the treatment goal?

Commonly employed treatment strategies for the management of specific tachyarrhythmias are outlined in Table 14.14.

Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams’ classification; Table 14.15 and Fig. 14.49).

Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class Ia drugs (e.g. disopyramide) lengthen the action potential, class Ib drugs (e.g. lidocaine) shorten the action potential, and class Ic (flecainide, propafenone) do not affect the duration of the action potential. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial (CAST) trials – class Ic agents) and in

Table 14.15 Vaughan Williams' classification of antiarrhythmic drugs

Class I	Membrane-depressant drugs (sodium-channel blockers)
Ia	Disopyramide
Ib	Lidocaine, mexiletine
Ic	Flecainide, propafenone
Class II	β -Adrenoceptor blocking drugs, e.g. atenolol, propranolol, esmolol
Class III	Prolong action potential, e.g. amiodarone, dronedarone, sotalol
Class IV	Calcium-channel blockers, e.g. verapamil, diltiazem
(Other	Adenosine, digoxin)

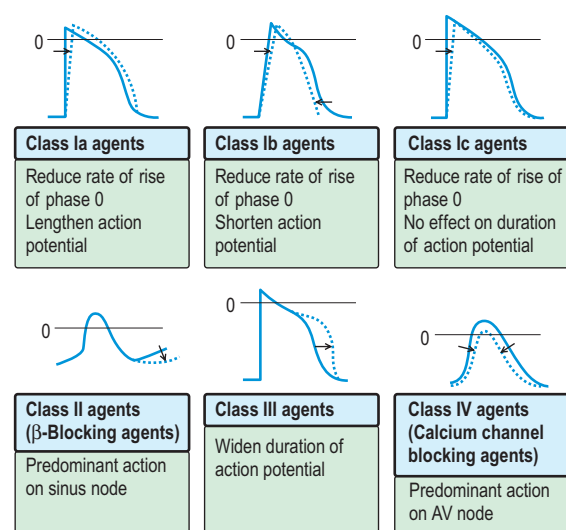

Figure 14.49 Vaughan Williams' classification of antiarrhythmic drugs based on their effect on cardiac action potentials. 0 = 0 mV. The dotted curves indicate the effects of the drugs.

patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this, class Ic agents such as flecainide and all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction, or other forms of significant structural heart disease.

Class II drugs

These antisympathetic drugs prevent the effects of catecholamines on the action potential. Most are β -adrenoceptor antagonists. Cardioselective beta-blockers (β_1) include metoprolol, bisoprolol, atenolol and acebutolol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general beta-blockers are anti-ischaemic and anti-adrenergic, and have proven beneficial effects in patients post-myocardial infarction (by preventing ventricular fibrillation) and in patients with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly in patients with coronary artery disease.

Class III drugs

These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current

(IKr) and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a beta-blocker.

Some drugs, such as ibutilide and dofetilide, are only available in some countries. Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy in contrast to most other antiarrhythmic drugs carries a low risk of proarrhythmia in patients with significant structural heart disease. Because it has many toxic and potentially serious side-effects, patients need to be counselled prior to commencing amiodarone and monitored at regular follow-up intervals. Dofetilide has been used to treat atrial fibrillation and flutter in patients with recent myocardial infarction and poor LV function. Dronedarone is a multichannel blocking drug which suppresses the recurrence of atrial fibrillation and reduces hospital admissions in patients with cardiovascular risk (ATHENA). However, it has proven harmful in patients with left ventricular dysfunction and heart failure (ANDROMEDA and PALLAS) and must not be used when heart failure is present.

Vernakalant is a multichannel blocker which is approved for the rapid intravenous medical cardioversion of new onset atrial fibrillation.

Class IV drugs

The non-dihydropyridine calcium channel blockers that reduce the plateau phase of the action potential are particularly effective at slowing conduction in nodal tissue. Verapamil and diltiazem are two drugs in this group. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

Drug therapy is commonly used for symptomatic relief in patients who do not have life-threatening tachyarrhythmias. Antiarrhythmic drugs have not been shown to prolong life. Patient safety is the main factor determining the choice of antiarrhythmic therapy and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts and class III agents are used in patients with structural heart disease, although exceptions occur.

In order to administer antiarrhythmic agents as safely as possible it is helpful to be familiar with the different proarrhythmia mechanisms and their main predisposing risk factors (Table 14.16).

Patients with structurally normal hearts and normal QT intervals, or with implantable defibrillators, are either at very low risk of proarrhythmia or are protected from any life-threatening consequences, and in these patients it is possible to persevere with drug therapy until an efficacious, well-tolerated agent is identified.

Catheter ablation

Radiofrequency catheter ablation is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed by placing three or four electrode catheters into the heart chambers in order to record and pace from various sites. Pacing the atria or the ventricles is used to trigger the tachycardia and to study the tachycardia mechanism. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or of a critical component of a macro-re-entry tachycardia. The following tachyarrhythmias can be readily ablated:

Table 14.16 Proarrhythmia mechanisms and the predisposing risk factors

Proarrhythmia mechanism	Drug	Predisposing risk factors
Torsades de pointes	Class I (disopyramide, procainamide, quinidine) Sotalol 'Pure' class III (ibutilide)	Baseline QT prolongation Female gender Hypokalaemia/diuretic use Clinical heart failure Advanced structural heart disease Conversion of AF to sinus rhythm
Atrial flutter with 1:1 AV conduction and wide QRS complexes	Class Ia (disopyramide, quinidine) Class Ic (flecainide, propafenone)	Risk reduced by adding an AV-nodal-slowing agent
'Late' sudden death (arrhythmic mechanism not clearly defined)	Class Ic (flecainide) Quinidine	Myocardial ischaemia

- AV node re-entry tachycardia (AVNRT)
- AV re-entry tachycardia (AVRT) with an accessory pathway, including WPW syndrome
- Normal heart VT
- Atrial flutter
- Atrial tachycardia
- Atrial fibrillation.

Symptomatic patients with a pre-excited ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These patients are commonly offered an ablation procedure if simple measures such as AV nodal slowing agents fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is >95%.

Patients with normal hearts and documented ventricular tachycardia should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

Catheter ablation is recommended in patients with atrial flutter that is not easily managed medically. Ablation of typical flutter is effective in 90–95% cases. In the direct comparison of catheter ablation and antiarrhythmic therapy, the rate of recurrence was significantly lower following ablation. Atrial tachycardia, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible despite optimal medical therapy. These patients experience a marked symptomatic improvement following AV node ablation and pacemaker implantation. Unlike other forms of catheter ablation this does not cure the arrhythmia; atrial fibrillation continues and anticoagulation is still required following ablation.

In *younger patients* with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy in or around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the atrium (pulmonary vein isolation). The

trigger is therefore eliminated and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size and no underlying heart disease (70–80% long-term success), but are presently time-consuming procedures (4 h or more) and are associated with some serious complications such as stroke, pericardial haemorrhage, pulmonary vein stenosis and atrio-oesophageal fistula in a small minority of patients (in experienced centres <2% altogether).

Implantable cardioverter-defibrillator (ICD)

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multi-centre prospective trials such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia.

The ICD recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are only a little larger than a pacemaker and are implanted in a pectoral position (Fig. 14.50). The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these patients have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result the ICD is now first-line therapy in the secondary prevention of sudden death.

Implantable cardioverter-defibrillators are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac arrest are as low as 10%. Therefore selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23–31% on top of

Figure 14.50 Implantable cardioverter-defibrillator. (a) X-ray of a 'dual-chamber' defibrillator in a left pectoral position with atrial and ventricular leads. **(b)** ECG showing the termination of ventricular fibrillation by the direct current shock at 20 J. Electrogram (EG) recorded internally from the ventricular lead of an ICD reveals chaotic ventricular activity consistent with ventricular fibrillation. This is confirmed by an electrocardiogram (lead V₂). The marker channel (MC) demonstrates that the device detects ventricular fibrillation correctly (FS, fibrillation sensing, lower line) and delivers an appropriate shock (CD) that terminates the arrhythmia and restores normal sinus rhythm (VS, ventricular sensing, lower line). Incidentally, atrial fibrillation is also detected before shock delivery (upper line on the marker channel).

conventional treatment, which included revascularization, beta-blockers and angiotensin-converting enzyme inhibitors. ICD combined with cardiac resynchronization therapy may improve both symptoms and life expectancy of patients with any degree of heart failure (COMPANION, CARE-HF and MADIT-CRT).

The following groups of patients may merit prophylactic ICD placement:

- Those with coronary artery disease; significant impairment of left ventricular function (LVEF ≤ 35 –40%), spontaneous non-sustained ventricular tachycardia in whom sustained ventricular tachycardia was induced by pacing the heart during an electrophysiological study
- Those with NYHA class III–IV heart failure (LVEF ≤ 35 %) in combination with cardiac resynchronization therapy, and in class I–II NYHA heart failure (LVEF ≤ 35 %) when LBBB is present
- Those with very poor LV function post-MI (LVEF ≤ 30 %)
- Those with dilated and hypertrophic cardiomyopathy, long QT syndrome and Brugada syndrome or other channelopathies who have a strong family history of sudden cardiac death.

HEART FAILURE

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological circulation.

Worldwide, the incidence of heart failure is variable but increases with advancing age. For example, in Scotland the prevalence of heart failure is high at 7.1 in 1000, increasing with age to 90.1 in 1000 among people over 85 years. In the UK, overall incidence is about 2 in 1000. Approximately 23 million people worldwide have heart failure.

Table 14.17 Causes of heart failure

Main causes

Ischaemic heart disease (35–40%)
Cardiomyopathy (dilated) (30–34%)
Hypertension (15–20%)

Other causes

Cardiomyopathy (undilated): hypertrophic, restrictive (amyloidosis, sarcoidosis)
Valvular heart disease (mitral, aortic, tricuspid)
Congenital heart disease (ASD, VSD)
Alcohol and drugs (chemotherapy – trastuzumab, imatinib)
Hyperdynamic circulation (anaemia, thyrotoxicosis, haemochromatosis, Paget's disease)
Right heart failure (RV infarct, pulmonary hypertension, pulmonary embolism, COPD)
Tricuspid incompetence
Arrhythmias (atrial fibrillation, bradycardia (complete heart block, the sick sinus syndrome))
Pericardial disease (constrictive pericarditis, pericardial effusion)
Infections (Chagas' disease), e.g. myocarditis

The prognosis of heart failure has improved over the past 10 years, but the mortality rate is still high with approximately 50% of patients dead at 5 years. Heart failure accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the commonest cause of heart failure in western countries.

The causes of heart failure are shown in Table 14.17.

Pathophysiology

When the heart fails, considerable changes occur to the heart and peripheral vascular system in response to the haemodynamic changes associated with heart failure (Table 14.18). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and

Table 14.18 Pathophysiological changes in heart failure

Ventricular dilatation
Myocyte hypertrophy
Increased collagen synthesis
Altered myosin gene expression
Altered sarcoplasmic Ca^{2+} -ATPase density
Increased ANP secretion
Salt and water retention
Sympathetic stimulation
Peripheral vasoconstriction

become pathophysiological. The development of pathological peripheral vasoconstriction and sodium retention in heart failure by activation of the renin-angiotensin-aldosterone system are a loss of beneficial compensatory mechanisms and represent cardiac decompensation. Factors involved are venous return, outflow resistance, contractility of the myocardium, and salt and water retention.

Venous return (preload)

In the intact heart, myocardial failure leads to a reduction of the volume of blood ejected with each heart beat and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling's law of the heart (p. 671) would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (Fig. 16.6, p. 871).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heart beat (ejection fraction) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume \times heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial and alveolar fluid, and to the occurrence of hepatic enlargement, ascites and dependent oedema, due to increased systemic venous pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise.

In very severe heart failure, the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain and kidneys, at the expense of the skin and muscle.

Outflow resistance (afterload) (see Fig. 14.5)

This is the load or resistance against which the ventricle contracts. It is formed by:

- Pulmonary and systemic resistance
- Physical characteristics of the vessel walls
- The volume of blood that is ejected.

An increase in afterload decreases the cardiac output. This results in a further increase of end-diastolic volume and dilatation of the ventricle itself, which further exacerbates the problem of afterload. This is expressed by Laplace's law:

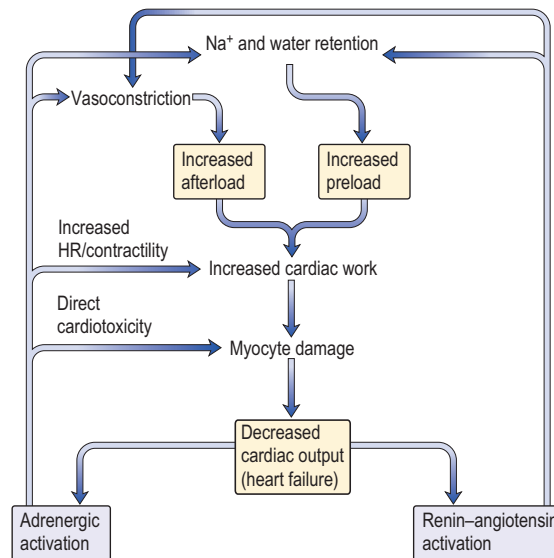

Figure 14.51 The compensatory physiological response to heart failure. Chronic activation of the renin-angiotensin and adrenergic systems results in a 'vicious cycle' of cardiac deterioration that further exacerbates the physiological response.

the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber (R): i.e. $T \propto PR$.

Myocardial contractility (inotropic state)

The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a downregulation of β -receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive, and this is a normal part of the Frank-Starling relationship (Fig. 14.5, p. 672). Conversely, myocardial depressants (e.g. hypoxia) decrease myocardial contractility (negative inotropism).

Neurohormonal and sympathetic system activation: salt and water retention

The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water and their accumulation in the interstitium, producing many of the physical signs of heart failure. Reduced cardiac output also leads to diminished renal perfusion, activating the renin-angiotensin system and enhancing salt and water retention (Fig. 12.5, p. 566), which further increases venous pressure (Fig. 14.51). The retention of sodium is in part compensated by the action of circulating atrial natriuretic peptides and antidiuretic hormone (see p. 650).

The interaction of haemodynamic and neurohumoral factors in the progression of heart failure remains unclear. Increased ventricular wall stress promotes ventricular dilatation and further worsens contractile efficiency. In addition, prolonged activation of the sympathetic nervous and renin-angiotensin-aldosterone systems exerts direct toxic effects on myocardial cells.

Myocardial remodelling in heart failure

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape and function owing to the

Figure 14.52 Ventricular remodelling in (a) ischaemic (MI) and (b) non-ischaemic heart failure, e.g. in cardiomyopathy.

influence of mechanical, neurohormonal and possibly genetic factors in several clinical conditions, including myocardial infarction, cardiomyopathy, hypertension and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for significant impairment of overall function of the heart as a pump (Fig. 14.52a). In cardiomyopathy, the process of progressive ventricular dilatation or hypertrophy occurs without ischaemic myocardial injury or infarction (Fig. 14.52b).

Changes in myocardial gene expression

Haemodynamic overload of the ventricle stimulates changes in cardiac contractile protein gene expression. The overall effect is to increase protein synthesis, but many proteins also switch to fetal and neonatal isoforms. Human myosin is composed of a pair of heavy chains and two pairs of light chains. Myosin heavy chains (MHC) exist in two isoforms, α and β , that have different contractile properties and ATPase activity. α -MHC predominates in the atria and β -MHC in the ventricles. In animal models, pressure overload results in a shift from α - β -MHC in the atria, in parallel with atrial size. This results in reduction in atrial contractility but reduced energy demands. This shift is less significant in the human ventricle, as the β -MHC isoform already predominates. Other genes affected in heart failure include those encoding Na^+/K^+ -ATPase, Ca^{2+} -ATPase and β_1 -adrenoceptors.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 14.3, p. 670). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 14.9, p. 674) controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Apoptosis

Apoptosis (or 'programmed cell death') of myocytes has been demonstrated in animal models of ischaemic

reperfusion, rapid ventricular pacing, mechanical stretch and pressure overload. Apoptosis is associated with irreversible congestive heart failure, and the spiral of ventricular dysfunction, characteristic of heart failure, results from the initiation of apoptosis by cytokines, free radicals and other triggers.

Natriuretic peptides (ANP, BNP and C-type)

Atrial natriuretic peptide (ANP) is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilatation and suppression of the renin-angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state. The renal response to ANP is attenuated in heart failure, probably secondarily to reduced renal perfusion, receptor downregulation, increased peptide breakdown, renal sympathetic activation and excessive renin-angiotensin activity.

Brain natriuretic peptide (BNP) (so called because it was first discovered in brain) is predominantly secreted by the ventricles, and has an action similar to that of ANP but greater diagnostic and prognostic value (p. 943).

C-type peptide, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

The therapeutic benefits of the natriuretic peptides have been investigated in two ways:

- The administration of *synthetic BNP* (nesiritide) has no effect on dyspnoea and is no longer recommended.
- Neutral endopeptidase (NEP) is a metalloendopeptidase involved in the degradation of a variety of vasoactive peptides (including ANP, BNP, CNP and bradykinin). In animal studies NEP inhibitors can produce diuresis and natriuresis. Omapatrilat is a combined angiotensin-converting enzyme inhibitor (ACEI) and NEP-I that is an effective antihypertensive agent, but it has not received FDA approval because of an increased risk of severe angio-oedema.

Endothelial function in heart failure

The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure, endothelium-dependent vasodilatation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor

substances, such as endothelin (ET). The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance. The major source of circulating ET in heart failure is the pulmonary vascular bed.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin-angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of endothelin antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral endothelin antagonists are being developed. Plasma concentrations of some cytokines, in particular TNF, are increased in patients with heart failure.

Antidiuretic hormone (vasopressin)

Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. High ADH concentration precipitates hyponatraemia which is an ominous prognostic indicator.

Clinical syndromes of heart failure

There are many causes of heart failure (Table 14.17) that can present suddenly with acute heart failure (AHF) or more insidiously with chronic heart failure (CHF).

Left ventricular systolic dysfunction (LVSD) is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension.

Right ventricular systolic dysfunction (RVSD) may be secondary to chronic LVSD but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy and adult congenital heart disease.

Diastolic heart failure is a syndrome consisting of symptoms and signs of heart failure with preserved left ventricular ejection fraction above 45–50% and abnormal left ventricular relaxation assessed by echocardiography. There is increased stiffness in the ventricular wall and decreased left ventricular compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Diastolic heart failure is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative).

The symptoms and signs of heart failure are:

Symptoms:

- Exertional dyspnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Fatigue.

Signs:

- Cardiomegaly
- Third and fourth heart sounds
- Elevated JVP
- Tachycardia
- Hypotension
- Bi-basal crackles
- Pleural effusion
- Peripheral ankle oedema
- Ascites
- Tender hepatomegaly.

The New York Heart Association classification of heart failure (Table 14.19) can be used to describe the symptoms of heart failure and limitation of exercise capacity, and is useful to assess response to therapy. It does not include left ventricular ejection fraction to determine severity of heart failure.

Diagnosis of heart failure

The diagnosis of heart failure should not be based on history and clinical findings; it requires evidence of cardiac dysfunction with appropriate investigation using objective measures of left ventricular structure and function (usually echocardiography). Similarly, the underlying cause of heart failure should be established in all patients (Table 14.20 and Fig. 14.53).

Table 14.19 New York Heart Association (NYHA) Classification of heart failure

Class I	No limitation. Normal physical exercise does not cause fatigue, dyspnoea or palpitations
Class II	Mild limitation. Comfortable at rest but normal physical activity produces fatigue, dyspnoea or palpitations
Class III	Marked limitation. Comfortable at rest but gentle physical activity produces marked symptoms of heart failure
Class IV	Symptoms of heart failure occur at rest and are exacerbated by any physical activity

Table 14.20 Diagnosis of heart failure (European Society of Cardiology guidelines)

Essential features (criteria 1 and 2)	
1.	Symptoms and signs of heart failure (e.g. breathlessness, fatigue, ankle swelling)
2.	Objective evidence of cardiac dysfunction (at rest, e.g. echocardiogram)
Non-essential features	
3.	Response to treatment directed towards heart failure (in cases where the diagnosis is in doubt)

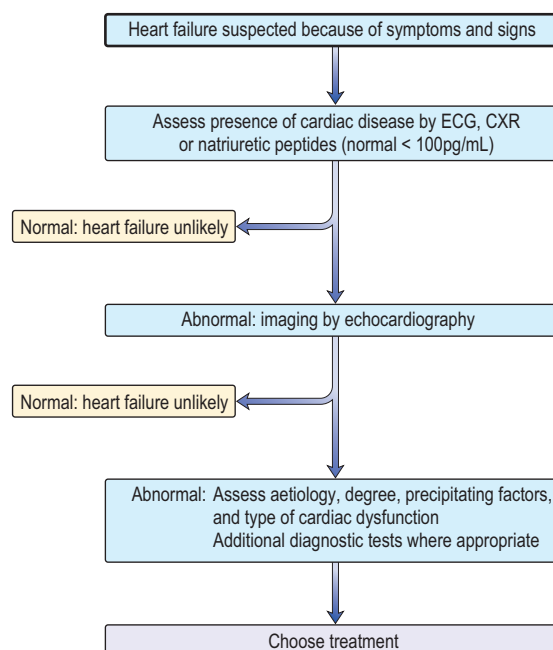

Figure 14.53 Algorithm for the diagnosis of heart failure. (Based on the European Society of Cardiology and NICE guidelines.)

Investigations in heart failure

- **Blood tests.** Full blood count, liver biochemistry, urea and electrolytes, cardiac enzymes in acute heart failure, BNP or N-terminal portion of proBNF (N-proBNP), thyroid function
- **Chest X-ray.** Look for cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines, and pulmonary oedema.
- **Electrocardiogram** for ischaemia, hypertension or arrhythmia.
- **Echocardiography.** Cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular heart disease, cardiomyopathies.
- **Stress echocardiography.** Assessment of viability in dysfunctional myocardium – dobutamine identifies contractile reserve in stunned or hibernating myocardium.
- **Nuclear cardiology.** Radionucleotide angiography (RNA) can quantify ventricular ejection fraction, single-photon-emission computed tomography (SPECT) or positron emission tomography (PET) can demonstrate myocardial ischaemia and viability in dysfunctional myocardium.
- **CMR (cardiac MRI).** Assessment of viability in dysfunctional myocardium with the use of dobutamine for contractile reserve or with gadolinium for delayed enhancement ('infarct imaging').
- **Cardiac catheterization.** Diagnosis of ischaemic heart failure (and suitability for revascularization), measurement of pulmonary artery pressure, left atrial (wedge) pressure, left ventricular end-diastolic pressure.
- **Cardiac biopsy.** Diagnosis of cardiomyopathies, e.g. amyloid, follow-up of transplanted patients to assess rejection.
- **Cardiopulmonary exercise testing.** Peak oxygen consumption (VO_2) is predictive of hospital admission and death in heart failure. A 6-minute exercise walk is an alternative.
- **Ambulatory 24-hour ECG monitoring (Holter).** In patients with suspected arrhythmia. May be used in patients with severe heart failure or inherited cardiomyopathy to determine if a defibrillator is appropriate (non-sustained ventricular tachycardia).

Treatment of heart failure

Treatment is aimed at relieving symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding disease progression and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires that any factor aggravating the failure should be identified and treated. Similarly, the cause of heart failure must be elucidated and where possible corrected. Community nursing programmes to help with drug compliance and to detect early deterioration may prevent acute hospitalization.

General lifestyle advice

Education

Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization.

Obesity control

Maintain desired weight and body mass index.

Dietary modification

Large meals should be avoided and, if necessary, weight reduction instituted. Salt restriction is necessary and foods rich in salt or added salt in cooking and at the table should be avoided. A low-sodium diet is unpalatable and of questionable value. In severe heart failure fluid restriction is necessary. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption. Omega-3 polyunsaturated fatty acids reduce mortality and admission to hospital.

Smoking

Smoking should be stopped, with help from anti-smoking clinics (p. 807) if necessary.

Physical activity, exercise training and rehabilitation

For patients with exacerbations of congestive cardiac failure, bed rest reduces the demands on the heart and is useful for a few days. Migration of fluid from the interstitium promotes a diuresis, reducing heart failure. Prolonged bed rest may lead to development of deep vein thrombosis; this can be avoided by daily leg exercises, low-dose subcutaneous heparin and elastic support stockings. Low-level endurance exercise (e.g. 20–30 min walking three or five times per week or 20 min cycling at 70–80% of peak heart rate five times per week) is actively encouraged in patients with compensated heart failure in order to reverse 'deconditioning' of peripheral muscle metabolism. Strenuous isometric activity should be avoided.

Vaccination

While prospective clinical trials are lacking, it is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza.

Air travel

This is possible for most patients, subject to clinical circumstances. Check with the airline – most have guidelines on who should travel.

Sexual activity

Tell patients on nitrates not to take phosphodiesterase type 5 inhibitors (e.g. sildenafil) as it may induce profound hypotension.

Driving

Driving motor cars and motorcycles may continue provided there are no symptoms that distract the driver's attention. The DVLA in the UK does not need to be notified. Symptomatic heart failure disqualifies patients from driving large lorries and buses. Re/licensing may be permitted provided that the LV ejection fraction is good (i.e. LVEF is >0.4), the exercise test requirements can be met and there is no other disqualifying condition.

Monitoring of heart failure patients

The clinical condition of a person with heart failure fluctuates, and repeated admissions to hospital is common. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary care health professionals.

Essential monitoring includes assessment of:

- functional capacity (e.g. VO_2 max, exercise tolerance test, echocardiography)

- fluid status (body weight, U&Es, clinical)
- cardiac rhythm (ECG, 24-hour tape).

Multidisciplinary team approach

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The use of multiple biomarkers, e.g. troponins and CRP, is of prognostic value. The multidisciplinary team should involve specialist healthcare professionals: heart failure nurse, dietitian, pharmacist, occupational therapist, physiotherapist and palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and 'end-of-life' issues.

Drug management (Table 14.21)

Figure 14.54 shows the stages of heart failure and the treatment options.

Diuretics

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride (p. 644). Loop diuretics (e.g. furosemide and bumetanide) and thiazide diuretics (e.g. bendroflumethiazide, hydrochlorothiazide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence that they affect survival. In severe heart failure patients, the combination of a loop and thiazide diuretic may be required.

Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Angiotensin-converting enzyme inhibitors (ACEI)

Trials have shown that in addition to producing considerable symptomatic improvement in patients with symptomatic heart failure, prognosis is markedly improved and development of heart failure is slowed. ACEI also benefit patients with asymptomatic heart failure following myocardial infarction (Fig. 12.5, p. 566). Thus ACEI improve survival in patients in all functional classes (NYHA I-IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia and renal dysfunction. The contraindications to their use include renal artery stenosis, pregnancy and previous angioedema. In patients with heart failure ACEI should be introduced gradually with a low initial dose and gradual titration with regular blood pressure monitoring. Serum creatinine should be measured concomitantly; potassium-sparing diuretics should be discontinued.

Angiotensin II receptor antagonists (ARA)

The angiotensin II receptor antagonists (ARA) (candesartan and valsartan) are indicated as second-line therapy in patients intolerant of ACEI. Unlike ACEI they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant to ACEI. Other trials (Val HeFT and ELITE II) have assessed other ARAs.

Table 14.21 Drugs used in heart failure

Drug	Dose (initial/maximum)	Precautions
ACE inhibitors/angiotensin II receptor antagonists		
Captopril	6.25 mg ×3 daily/25–50 mg ×3 daily	Monitor renal function and avoid if baseline serum creatinine >250 μmol/L or baseline BP <90 mmHg
Enalapril	2.5 mg daily/10 mg ×2 daily	
Ramipril	1.25–2.5 mg daily/2.5–5 mg ×2 daily	
Candesartan	4 mg daily/32 mg daily	
Valsartan	80 mg daily/320 mg daily	
Losartan	50 mg daily/100 mg daily	
Beta-blockers		
Bisoprolol	1.25 mg daily/10 mg daily	Caution in obstructive airways disease, bradyarrhythmias Avoid in acute heart failure until cardiovascularly stable
Carvedilol	3.125 mg daily/50 mg daily	
Nebivolol	1.25 mg daily/10 mg daily	
Diuretics		
Furosemide	20–40 mg daily/max. 250–500 mg daily	Monitor renal function and check for hypokalaemia and hypomagnesaemia
Bumetanide	0.5–1.0 mg daily/max. 5–10 mg daily	
Bendroflumethiazide	2.5 mg daily/max. 10 mg daily	For severe heart failure
Metolazone	2.5 mg daily/max. 10 mg daily	
Aldosterone antagonists		
Spironolactone	12.5–25 mg daily/max. 50–200 mg daily (lower if on ACE inhibitor)	Monitor renal function, check for hyperkalaemia, gynaecomastia with spironolactone
Eplerenone	25 mg daily/50 mg daily	
Cardiac glycosides		
Digoxin	0.125–0.25 mg daily (reduce dose in elderly or if renal impairment)	Caution in renal impairment, conduction disease and if on amiodarone
Vasodilators		
Isosorbide dinitrate	20–40 mg ×3 daily	Caution: sick sinus syndrome; AV block
Hydralazine	37.5–75 mg ×3 daily	
Ivabradine	5 mg daily (max. 7.5 mg ×2 daily)

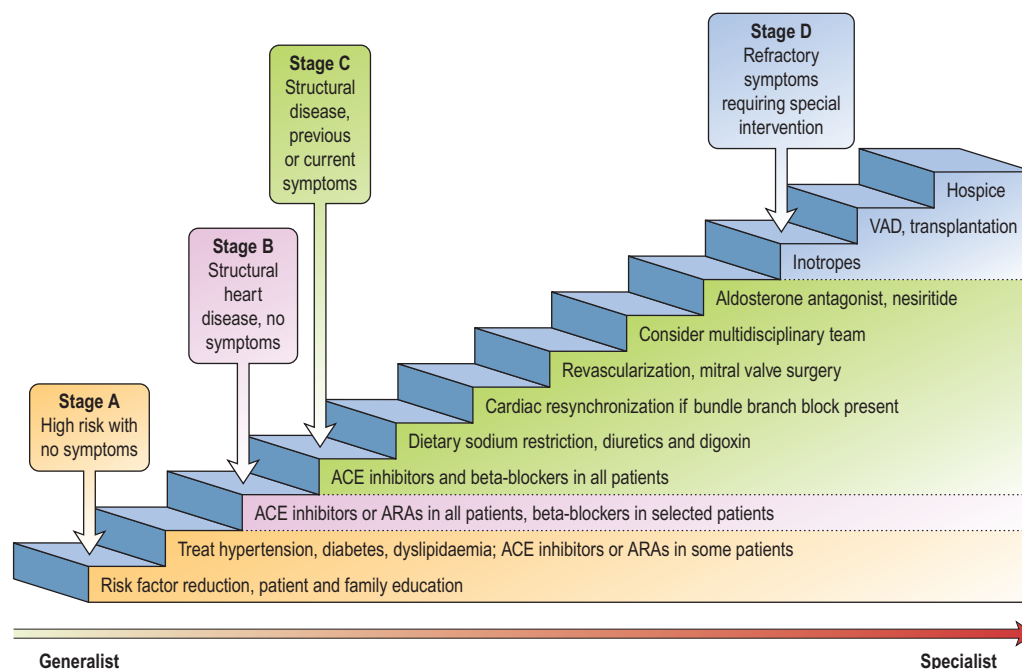

Figure 14.54 Stages of heart failure and treatment options for systolic heart failure. ARA, angiotensin II receptor antagonist; ACE, angiotensin-converting enzyme; VAD, ventricular assisted device.

Beta-blockers

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS, CIBIS II, MERIT-HF, COMET, SENIORS) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol and carvedilol reduce mortality in any grade of heart failure.

Nebivolol is used in the treatment of stable mild-moderate heart failure in patients over 70 years old.

In patients with heart failure, only evidence-based beta-blockers from successful trials should be used. In patients with significant heart failure, beta-blockers are started at a low dose and gradually increased.

Aldosterone antagonists

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with heart failure. In RALES, spironolactone reduced total mortality by 30% in patients with severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS, eplerenone given to patients with an acute myocardial infarction and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

Cardiac glycosides

Digoxin is a cardiac glycoside that is indicated in patients in atrial fibrillation with heart failure. It is used as add-on therapy in symptomatic heart failure patients already receiving ACEI and beta-blockers. The DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure.

Vasodilators and nitrates

The combination of hydralazine and nitrates reduces after-load and pre-load and is used in patients intolerant of ACEI or ARA. The Veterans Administration Cooperative Study demonstrated that the combination of hydralazine (with

nitrates) improved survival in patients with chronic heart failure. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

Inotropic and vasopressor agents

Intravenous inotropes and vasopressor agents (see Table 14.25) are used in patients with chronic heart failure who are not responding to oral medication. Although they produce haemodynamic improvements they have not been shown to improve long-term mortality when compared with placebo.

Other medications

In hospital, all patients require prophylactic anticoagulation. Heart failure is associated with a four-fold increase in the risk of a stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in patients with sinus rhythm with a history of thromboembolism, left ventricular thrombus or aneurysm. In patients with known ischaemic heart disease antiplatelet therapy (aspirin, clopidogrel) and statin therapy should be continued. Arrhythmias are frequent in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is no evidence to support this and it may increase mortality. In the Sudden Cardiac Death Heart Failure Trial (SCD-HeFT), amiodarone showed no benefit compared to placebo in patients with impaired left ventricular function and mild-moderate heart failure (whereas an ICD reduced mortality by 23% compared to placebo). Patients with heart failure and symptomatic ventricular arrhythmias should be assessed for suitability for an ICD.

Ivabradine, which inhibits the I_f channels in the sinoatrial node, slows the heart rate and in the SHIFT study was associated with a reduction in cardiovascular mortality and hospital admission for worsening heart failure in patients in sinus rhythm with chronic heart failure and left ventricular dysfunction (LVEF $\leq 35\%$) when compared to placebo.

Non-pharmacological treatment of heart failure

Revascularization

While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10–20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include age, symptoms and evidence for reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning

'Hibernating' myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is due to reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, e.g. with repeated exercise in a patient with coronary artery disease.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal, i.e. there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with coronary artery disease can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization and is estimated to be 33% of such patients. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging techniques, cardiovascular magnetic resonance and positron emission tomography.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring which seems untreatable, whereas reversible hibernating and stunning respond to coronary revascularization.

Biventricular pacemaker or implantable cardioverter-defibrillator

Pacemakers (Fig. 14.55) are indicated in patients with sinoatrial disease and atrioventricular conduction block. Pacemakers are also valuable in patients without AV block

Figure 14.55 Implanted biventricular pacing with ICD device.

but with prolonged PR intervals, left bundle branch block and severe mitral regurgitation. In patients with heart failure and left bundle branch block and NYHA class III heart failure (MUSTIC study) biventricular pacing was more beneficial than conventional right ventricular pacing. The results showed an improvement in symptoms and exercise tolerance. The effect on prognosis is being addressed by an ongoing trial (CARE HF).

Biventricular pacing can also be used in patients not responding to therapy in the following situations:

- Systolic heart failure
- Non-reversible cause
- Highly symptomatic (New York Heart Association class III/IV)
- On optimal medical therapy
- Ventricular dys-synchrony: left bundle branch block (QRS >120 ms)
- Sinus rhythm, and possibly atrial fibrillation
- Significant mitral regurgitation.

New guidelines recommend advanced pacing technologies should be used for cardiac resynchronization therapy (CRT) in selected patients with heart failure. Atrio-biventricular pacing has been shown to improve symptoms and reduce admission to hospital in patients with left bundle branch block and heart failure with poor LV function. The use of combined implantable defibrillators and atrio-biventricular pacemakers for patients with heart failure is likely to increase. One large trial (COMPANION) shows 21% reduction in all-cause mortality and all-cause admissions to hospital in the groups receiving biventricular pacing. ICD therapy in patients with NYHA (classes I and II, see Table 14.19) has shown a reduction in mortality compared with placebo and amiodarone.

Cardiac transplantation

Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life expectancy is <6 months. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and is 75% at 5 years. Irrespective of survival, quality of life is dramatically improved for the majority of patients. The availability of heart transplantation is limited.

Heart allografts do not function normally. Cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin-angiotensin-aldosterone regulation. Some patients develop a 'stiff heart' syndrome, caused by rejection, denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inappropriately small donor heart can also result in elevated right and left heart pressure.

The complications of heart transplantation are summarized in Table 14.22. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30–50% of patients at 5 years. It is due to a 'vascular' rejection process in conjunction with hypertension and hyperlipidaemia.

There are specific contraindications to cardiac transplantation (Table 14.23); notably, high pulmonary vascular resistance is an absolute contraindication. Several options to transplantation are available: cardiomyoplasty (augmentation of left ventricular contraction by wrapping a latissimus dorsi muscle flap around the ventricle) and the Batista procedure (surgical ventricular size reduction and remodelling the

geometry of the left ventricle). Both procedures have a high mortality and limited evidence of substantial benefit in the medium term.

Acute heart failure

Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This causes severe dyspnoea and fluid accumulates in the interstitium and alveolar spaces of the lung (pulmonary oedema). AHF has a poor prognosis with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with *acute pulmonary oedema* the in-hospital mortality rate is 12% and by 12 months this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure (PCWP), low serum sodium concentration, increased left ventricular end-diastolic dimension on echo and low oxygen consumption.

The aetiology of AHF is similar to chronic heart failure:

- People with **ischaemic heart disease** present with an acute coronary syndrome or develop a complication of a myocardial infarct, e.g. papillary muscle rupture or ventricular septal defect requiring surgical intervention.
- People with **valvular heart disease** also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe aortic regurgitation.
- People with **hypertension** present with episodes of ‘flash’ pulmonary oedema despite preserved left ventricular systolic function.
- In both **acute and chronic kidney disease** fluid overload and a reduced renal excretion will produce pulmonary oedema.

Table 14.24 Clinical syndromes of acute heart failure (AHF)

Type	Clinical features
Acute decompensated heart failure	Mild features of heart failure, e.g. dyspnoea
Hypertensive AHF	High blood pressure, preserved left ventricular function, pulmonary oedema on CXR
Acute pulmonary oedema	Tachypnoea, orthopnoea, pulmonary crackles, oxygen saturation <90% on air, pulmonary oedema on CXR
Cardiogenic shock	Systolic blood pressure <90 mmHg, mean arterial pressure drop >30 mmHg, urine output <0.5 mL/kg per hour, heart rate >60 b.p.m.
High output heart failure	Warm peripheries, pulmonary congestion, blood pressure may be low, e.g. septic shock
Right heart failure	Low cardiac output, elevated jugular venous pressure, hepatomegaly, hypotension
Modified from the European Society of Cardiology.	

- **Atrial fibrillation** is frequently associated with AHF and may require emergency cardioversion.

Several clinical syndromes of AHF can be defined (Table 14.24). In a clinical environment both the Killip score (p. 739, based on a cardiorespiratory clinical assessment) and Forrester (based on right catheterization findings) classification are used to provide therapeutic and prognostic information.

Pathophysiology

The pathophysiology of AHF is similar to chronic heart failure with activation of the renin-angiotensin-aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g. in acute coronary syndromes) results in myocardial stunning (p. 721) that exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow) that may recover with successful revascularization.

Diagnosis

In a patient presenting with symptoms and signs of heart failure a structured assessment should result in the clinical diagnosis of AHF and direct initial treatment to stabilize the patient. Initial investigations performed in the emergency room should include the following:

- **A 12-lead ECG** for acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, valvular heart disease, left bundle branch block
- **A chest X-ray** (cardiomegaly, pulmonary oedema, pleural effusion, non-cardiac disease)
- **Blood investigations** (serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, CRP and D-dimer)
- **Plasma BNP or NTproBNP** (BNP >100 pg/mL or NTproBNP >300 pg/mL indicates heart failure)
- **Transthoracic echocardiography** should be performed without delay to confirm the diagnosis of heart failure (p. 686) and possibly identify the cause.

If the baseline investigations confirm AHF, then treatment should be commenced.

Treatment

The goals of treatment in a patient with AHF include:

- Immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- Reduction in length of hospital stay and hospital readmissions
- Reduction in mortality from heart failure.

Patients with AHF should be managed in a high-care area with regular measurements of temperature, heart rate, blood pressure and cardiac monitoring. All patients require prophylactic anticoagulation with low molecular weight heparin, e.g. enoxaparin 1 mg/kg s.c. $\times 2$ daily.

Patients with haemodynamic compromise may require arterial lines (invasive blood pressure monitoring and arterial gases), central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery cannulation (calculation of cardiac output/index, peripheral vasoconstriction and pulmonary wedge pressure).

Initial therapy (Fig. 14.56, Table 14.25) includes oxygen, diuretics (e.g. i.v. furosemide 50 mg) and vasodilator therapy (e.g. glyceryl trinitrate infusion 10–200 $\mu\text{g}/\text{min}$) if the blood pressure is maintained (systolic >85 mmHg). Inotropic support (see p. 887) with dobutamine, phosphodiesterase

inhibitors or levosimendan can be added in patients who do not respond to the initial therapy (Fig. 14.56). If blood pressure is low, use noradrenaline (norepinephrine).

Patients with profound hypotension may require inotropes and vasopressors to improve the haemodynamic status and alleviate symptoms, but these have not been shown to improve mortality. Non-invasive CPAP/NIPPV (see p. 895) has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via masks; mortality is however unaffected.

Mechanical assist devices

Mechanical assist devices can be used in patients who fail to respond to standard medical therapy but in whom there is either transient myocardial dysfunction with likelihood of recovery (e.g. post anterior myocardial infarction treated with coronary angioplasty) or a bridge is needed to cardiac surgery, including transplantation.

Ventricular assist devices (VAD) (Fig. 14.57) Ventricular assist devices are mechanical devices that replace or help the failing ventricles in delivering blood around the body. A left ventricular assist device (LVAD) receives blood from the left ventricle and delivers it to the aorta; a right ventricular assist device (RVAD) receives blood from the right ventricle and delivers it to the pulmonary artery. The devices can be extracorporeal (suitable for short-term support) or intracorporeal (suitable for long-term support as a bridge to transplantation or as destination therapy in patients with end-stage heart failure not candidates for transplantation). The main problems with VADs include thromboembolism, bleeding, infection and device malfunction.

CORONARY ARTERY DISEASE

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential

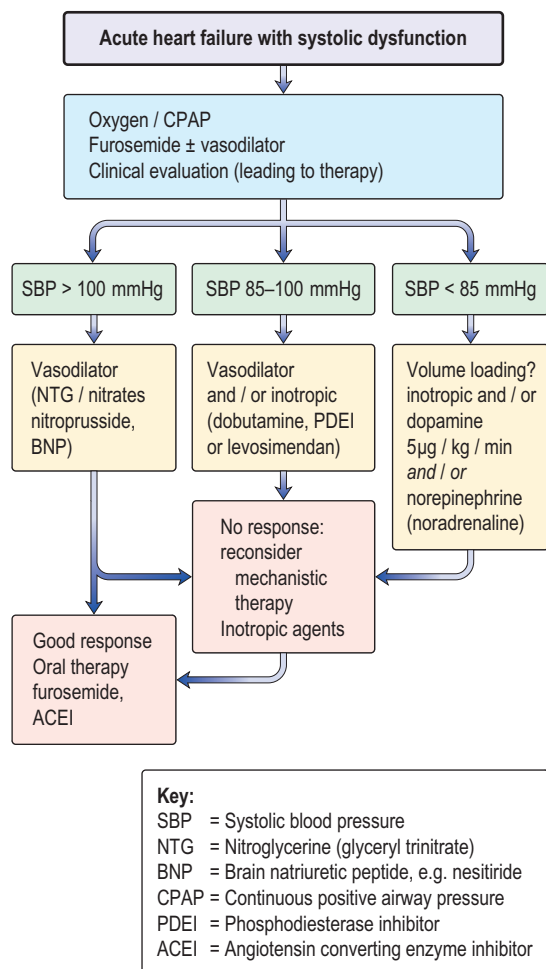

Figure 14.56 Algorithm for the management of acute heart failure with systolic dysfunction. (From Nieminen MS, Böhm M, Cowie MR et al. *European Heart Journal* 2005; 26:384–416, Figure 6, with permission from Oxford University Press and the European Society of Cardiology.)

Figure 14.57 Left ventricular assist device. (From Moser DK, Riegel B. *Cardiac Nursing*. Philadelphia: Saunders; 2007: 981, with permission of Elsevier.)

Table 14.25 Pharmacological therapy in acute heart failure

Drug	Dose	Indications/mechanism of action
Myocardial oxygenation		
Oxygen	35–50% inspired oxygen concentration	Ensure airway is patent and maintain arterial saturation 95–98%
Non-invasive ventilation (NIPPV), e.g. CPAP		Use if failing to maintain arterial saturation Increases pulmonary recruitment and functional residual capacity – reduces work of breathing
Intubation/mechanical ventilation		Use if failing to maintain arterial saturation and patient fatigue (reduced respiratory rate, increased arterial CO ₂ , confusion)
Opiate		
Morphine	2.5–5.0 mg i.v. (with anti-emetic metoclopramide 10 mg i.v.)	Use in agitated patient Relieves dyspnoea, venous and arterial dilatation, heart rate reduction
Anti-thrombin		
Low-molecular-weight heparin	e.g. enoxaparin 1 mg/kg s.c. x2 daily ACS or 40 mg s.c. daily prophylaxis	Use in patients with AHF and ACS or atrial fibrillation or DVT prophylaxis Caution if creatinine clearance <30 mL/min
Vasodilator		
Glyceryl trinitrate	10–200 µg/min i.v. infusion	Reduces pulmonary congestion, low dose venodilation and high dose arterial vasodilation – reduce pre- and after-load Ensure BP >85–90 mmHg
Sodium nitroprusside	0.3–5 µg/kg per min i.v. infusion	Use in severe AHF where predominantly high after-load, e.g. hypertensive AHF Needs arterial BP monitoring for profound hypotension
Diuretic		
Furosemide	Bolus 40–100 mg i.v. or infusion 5–40 mg/h	Low doses produce vasodilation and reduce right atrial and PCWP and promotes diuresis Need to monitor sodium, potassium and creatinine
Inotrope		
Dopamine	Low dose <2 µg/kg per min Medium dose >2 µg/kg per min High dose >5 µg/kg per min	Low dose acts on peripheral dopamine receptors to produce vasodilation (renal, splanchnic, coronary, cerebrovascular) and may improve diuresis Medium dose acts on β-receptors to increase myocardial contractility and cardiac output High dose acts on α-receptors causing vasoconstriction and increasing total peripheral resistance (increases after-load, PAP)
Dobutamine	2–20 µg/kg per min (may need high dose in patients on beta-blockers)	Stimulates β ₁ and β ₂ receptors producing vasodilation. Increases heart rate and cardiac output and diuresis as improved haemodynamics
Milrinone	Bolus 25–75 µg/kg over 10–20 min then 0.375–0.75 µg/kg per min	Inhibits phosphodiesterase and maintains cAMP Increases cardiac output and stroke volume, reduces PAP/PCWP/total peripheral resistance/ BP
Levosimendan	Bolus 12–24 µg/kg over 10 min then 0.05–2 µg/kg per min	Calcium sensitization of contractile proteins and opening of potassium channels Increased cardiac output, stroke volume and heart rate Reduced PCWP and blood pressure
Vasopressor		
Norepinephrine	0.2–1.0 µg/kg per min	Stimulates α receptors and increases total peripheral resistance and blood pressure

Cardiac glycoside		
Digoxin	0.5 mg i.v. repeated after 2–6 h	Inhibits myocardial sodium/potassium ATPase leading to increased calcium and sodium exchange Increases cardiac output and slows AV conduction Use in AF; avoid in ACS

myocardial nutrients) and the myocardial demand for these substances.

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

- Atheroma
- Thrombosis
- Spasm
- Embolus
- Coronary ostial stenosis
- Coronary arteritis (e.g. in SLE).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:

- Anaemia
- Carboxyhaemoglobulinaemia
- Hypotension causing decreased coronary perfusion pressure.

An increased demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly occurs as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. However, over the last decade, the mortality rate in the UK has fallen considerably. In 2009, 1 in 5 male and 1 in 8 female deaths were from coronary artery disease; approximately 82 000 deaths in the UK (www.bhf.org.uk/heart-health/statistics/mortality.aspx). It has been estimated that by 2010, 60% of the world's heart disease occurred in India. Sudden cardiac death is a prominent feature of CAD. One in every six coronary attacks present with sudden death as the first, last and only symptom.

Process of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbid hypertension), biochemical abnormalities (e.g. elevated LDL, diabetes mellitus), immunological factors (e.g. free radicals from smoking), inflammation (e.g. infection such as *Chlamydomphila pneumoniae*) and genetic alteration may contribute to the initial endothelial 'injury' or dysfunction, which is believed to trigger atherogenesis.

The development of atherosclerosis follows the endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as 'fatty streaks'. The 'fatty streak' progresses with the appearance of extracellular lipid within the endothelium ('transitional plaque'). Release of cytokines such as platelet-derived growth factor and transforming growth factor- β (TGF- β) by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the

Figure 14.58 The mechanisms for the development of thrombosis on plaques.

adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an 'advanced or raised fibrolipid plaque'. The 'advanced plaque' may grow slowly and encroach on the lumen or become unstable, undergo thrombosis and produce an obstruction ('complicated plaque').

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 14.58):

- The **first process** is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Subendocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.
- The **second process** is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen, is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 14.59). Figure 14.60 shows an actual plaque rupture.

Risk factors for coronary artery disease – primary and secondary prevention

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of 'risk' factors are known to predispose to the condition (Table 14.26). Some of these, such as age, gender, race and family history, cannot be changed, whereas

Personality
Obesity
Gout
Soft water
Drugs, e.g. contraceptive pill, nucleoside analogues, COX-2 inhibitors, rosiglitazone
Heavy alcohol consumption

other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can be modified.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with intermittent claudication have a two- to four-fold increased risk of CAD, stroke, or heart failure. Following initial myocardial infarction (MI), there is a 3–6-fold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased two-fold.

The disease can be asymptomatic in its most severe form, with one in three myocardial infarctions going unrecognized. Some 30–40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

Primary prevention can be defined as the prevention of the atherosclerotic disease process and **secondary prevention** as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

Traditional risk factors

Age

CAD rates increase with age. Atherosclerosis is rare in childhood, except in familial hyperlipidaemia, but is often detectable in young men between 20 and 30 years of age. It is almost universal in the elderly in the West. Atheromatous lesions in the elderly are often complicated by calcification.

Gender

Men have a higher incidence of coronary artery disease than premenopausal women. However, after the menopause, the incidence of atheroma in women approaches that in men. The reasons for this gender difference are not clearly understood, but probably relate to the loss of the protective effect of oestrogen.

Family history

CAD is often found in several members of the same family. Because the disease is so prevalent and because other risk factors are familial, it is uncertain whether family history, *per se*, is an independent risk factor. A positive family history is generally accepted to refer to those in whom a first-degree relative has developed ischaemic heart disease before the age of 50 years.

Smoking

In men, the risk of developing CAD is directly related to the number of cigarettes smoked (see p. 807). It is estimated that about 20% of deaths from CAD in men and 17% of deaths from CAD in women are due to smoking. Evidence suggests that each person stopping smoking will reduce his/her own risk by 25%. The risk from smoking declines to almost normal after 10 years of abstinence.

Diet and obesity

Diets high in fats are associated with ischaemic heart disease, as are those with low intakes of antioxidants (i.e. fruit and vegetables). Supplementation with antioxidants has been shown to be unhelpful in RCTs (p. 211).

Stone GW, Maehara A, Lansky AJ et al., for the PROSPECT Investigators. A prospective natural-history study of coronary atherosclerosis. *N Engl J Med* 2011; 364:226–235.

It is estimated that up to 30% of deaths from CAD are due to unhealthy diets (see p. 200). The dietary changes which would help to reduce rates of CAD include a reduction in fat, particularly saturated fat intake, a reduction in salt intake and an increase in carbohydrate intake. The consumption of fruit and vegetables should be increased by 50%, to about 400 g/day, which is equivalent to at least five daily portions (see Box 5.2).

There is overwhelming evidence from clinical trials that modification of the diet has a significant impact on the risk of CVD in both the primary and secondary prevention settings.

Weight. Patients who are overweight and those who are obese have an increased risk of CAD. It is estimated that about 5% of deaths from CAD in men and that 6% of such deaths in women are due to obesity (a body mass index (BMI) of $>30 \text{ kg/m}^2$).

The adverse effect of excess weight is more pronounced when the fat is concentrated mainly in the abdomen. This is known as central obesity (visceral fat) and can be identified by a high waist/hip ratio.

Exercise. Reduction in weight by diet and exercise not only lowers the incidence of CVD but also diabetes/insulin resistance. It is estimated that about 36% of deaths from CAD in men and 38% of deaths from CAD in women are due to lack of physical activity. To produce the maximum benefit the activity needs to be regular and aerobic. Aerobic activity involves using the large muscle groups in the arms, legs and back steadily and rhythmically so that breathing and heart rate are significantly increased.

It is recommended that adults should participate in a minimum of 30 minutes of at least moderate intensity activity (such as brisk walking, cycling or climbing the stairs) on ≥ 5 days of the week.

Hypertension

Both systolic and diastolic hypertension are associated with an increased risk of CAD. Both drug treatment and lifestyle changes – particularly weight loss, an increase in physical activity and a reduction in salt and alcohol intake – can effectively lower blood pressure.

It is estimated that 14% of deaths from CAD in men and 12% of deaths from CAD in women are due to a raised blood pressure (defined as a systolic blood pressure of $\geq 140 \text{ mmHg}$, or a diastolic blood pressure of $\geq 90 \text{ mmHg}$) and that 6% of deaths from CAD in the UK could be avoided if the numbers of people who have high blood pressure were to be reduced by 50%.

Hyperlipidaemia

High serum cholesterol, especially when associated with a low value of high-density lipoproteins (HDL), is strongly associated with coronary atheroma. There is increasing evidence that high serum triglyceride (TG) is also independently linked with coronary atheroma (see p. 1034).

Familial hypercholesterolaemia combined with hypertriglyceridaemia and remnant hyperlipidaemia are also associated with increased risk of coronary atherosclerosis.

Measurement of the fasting lipid profile (total cholesterol, low- and high-density lipoproteins and triglycerides) should be performed on all people with an increased risk of cardiac disease.

The risk of CAD is directly related to serum cholesterol levels. Serum cholesterol levels can be reduced by drugs, physical activity and by dietary changes, in particular a reduction in the consumption of saturated fat. It is estimated that 45% of deaths from CAD in men and 47% of deaths

from CAD in women are due to a raised serum cholesterol level (in this case $>5.2 \text{ mmol/L}$) and that 10% of deaths from CAD in the UK could be avoided if everyone in the population had a serum cholesterol level of $<6.5 \text{ mmol/L}$.

Different guidelines give slightly different advice for managing high levels of serum cholesterol (hyperlipidaemia). The National Service Framework for coronary heart disease in England includes guidelines on the prevention of CAD in clinical practice and suggests a cholesterol target of $<5.0 \text{ mmol/L}$ for both primary and secondary prevention.

High-density lipoprotein cholesterol (HDL-cholesterol) is the fraction of cholesterol that removes cholesterol (via the liver) from the blood. Low levels of HDL-cholesterol are associated with an increased risk of CAD and a worse prognosis after a heart attack. Guidelines on HDL-cholesterol generally recommend treatment for those with concentrations $<1.0 \text{ mmol/L}$. HDL increases with exercise, alcohol in moderation, not smoking and when TG is lowered.

A 1% reduction in cholesterol levels reduces risks of CAD by 2–3%. Hyperlipidaemia can be treated as follows:

- **Statins:** 24–30% reduction in mortality in primary and secondary prevention will be achieved if a statin (pravastatin or simvastatin) is given. Up to 50% reduction is achieved if the dose of statin (e.g. atorvastatin) is titrated to achieve a target LDL of $<2.6 \text{ mmol/L}$.
- **Fibrates** result in a significant reduction in CAD events in diabetics and patients with high TG and low HDL.
- **Diet:** the so-called Mediterranean diet (p. 198) has resulted in a 75% reduction in CAD events in post-myocardial infarction patients.

Angiographic studies have shown that lowering the serum cholesterol can slow the progression of coronary atherosclerosis, and can cause regression of disease. Large clinical trials have shown that lipid lowering, usually with a statin, can decrease total mortality and new coronary events, and reduce the need for revascularization. Management of hypercholesterolaemia is described in detail on page 1037.

Diabetes mellitus

Diabetes, an abnormal glucose tolerance or raised fasting glucose, is strongly associated with vascular disease.

Diabetes substantially increases the risk of CAD. Men with type 2 diabetes have a two- to four-fold greater annual risk of CAD, with an even higher (3–5-fold) risk in women with type 2 diabetes.

Diabetes not only increases the risk of CAD but also magnifies the effect of other risk factors for CAD such as raised cholesterol levels, raised blood pressure, smoking and obesity.

Other risk factors

Although there is general agreement on established cardiovascular risk factors, epidemiological research continues to identify or evaluate additional risk factors that contribute to the occurrence of atherosclerotic CVD and warrant further clarification.

Sedentary lifestyle

Lack of exercise is an independent risk factor for CAD equal to hypertension, hyperlipidaemia and smoking. Regular exercise probably protects against its development (see above).

Psychosocial wellbeing

Four different types of psychosocial factors have been found to be most consistently associated with an increased risk of

FURTHER READING

Berry JD et al. Lifetime risks of cardiovascular disease. *N Engl J Med* 2012; 366:321–329.

CAD: work stress, lack of social support, depression (including anxiety) and personality (particularly hostility).

Alcohol

Moderate alcohol consumption (one or two drinks per day) is associated with a reduced risk of CAD. At high levels of intake – particularly in ‘binges’ – the risk of CAD is increased. It is currently advised that ‘regular consumption of between three and four units a day by men’ and ‘between two and three units a day by women of all ages will not lead to any significant health risk’.

Genetic factors

A number of genetic factors have been linked with coronary artery disease. The angiotensin-converting enzyme (ACE) gene contains an insertion/deletion (I/D) polymorphism, the DD genotype of which has been associated with a predisposition to CAD and myocardial infarction.

Lipoprotein(a)

High plasma Lp(a) concentrations are associated with CAD and, although probably not an independent risk factor, elevated plasma Lp(a) increases the CAD risk associated with more traditional risk factors.

Coagulation factors

Serum fibrinogen is strongly, consistently and independently related to CAD risk. The pathophysiological mechanism by which fibrinogen levels mediate coronary disease risk is related to its effect on the coagulation cascade, platelet aggregation, endothelial function and smooth muscle cell proliferation and migration.

High levels of *coagulation factor VII* are also a risk factor. Polymorphisms of the factor VII gene may increase the risk of myocardial infarction.

Homocysteine, an amino acid regulated by vitamins B₁₂, B₆ and folate, is another factor that has been associated with CAD and atherosclerosis (see p. 212). Homocysteinaemia is a major risk factor in the pathogenesis of CAD and a strong predictor of mortality in this group. Plasma levels of homocysteine are influenced by a variety of genetic and non-genetic factors. The mechanism associating hyperhomocysteinaemia with atherosclerosis is its adverse effect on vascular endothelium. Folic acid in low doses may ameliorate this process.

C-reactive protein (CRP)

CRP is linked with future risk of coronary events independently of the traditional risk factors but its use as a marker for subclinical atherosclerosis and cardiovascular risk has been questioned.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs that are specific inhibitors of cyclo-oxygenase-2 (COX-2) have been shown to increase cardiovascular risk and mortality. Rofecoxib has already been withdrawn.

Prevention policy

The priorities for CVD prevention in clinical practice are:

- Patients with established CAD, PVD and cerebrovascular atherosclerotic disease
- Asymptomatic individuals who are at high risk of developing atherosclerotic disease because of multiple risk factors resulting in a 10-year risk of >5% now (or if extrapolated to age 60) for developing a fatal event, i.e. those with markedly raised levels of single risk factors:
 - cholesterol >8 mmol/L
 - LDL cholesterol >6 mmol/L
 - BP >180/110 mmHg.

- All patients with diabetes.
- Close relatives of:
 - patients with early-onset atherosclerotic cardiovascular disease
 - asymptomatic individuals at a particularly high risk.
- Other individuals encountered in routine clinical practice.

Risk estimation for CVD prevention in the asymptomatic population

Patients with established CVD have declared themselves to be at high total risk of further vascular events. Therefore they require the most intense lifestyle intervention, and where appropriate drug therapies.

However, in the majority of asymptomatic, apparently healthy people, preventative actions should be guided in accordance with the total CVD risk level. Indeed, risk factor management decisions should usually not be based on considerations of a single modestly raised factor.

To evaluate candidates for the major cardiovascular events cost-effectively, multivariate risk profiles have been formulated; these facilitate targeting those at high risk for preventative measures.

The Joint British Societies, the European Society of Cardiology and the American Heart Association have emphasized the importance of these risk profiles for motivating as well as reassuring patients and in assisting in selecting therapy. They concluded that these scores direct healthcare professionals to look at the whole patient and to recognize the cumulative nature of risk factors (Fig. 14.61). However, not all practitioners agree with this approach (see p. 1038).

National Service Framework (NSF)

The UK's NSF includes a nurse-led audited approach to reduce CAD by lowering saturated fat intake, increasing exercise and, most relevant, decreasing/stopping smoking. The hypertension treatment targets are 140/85 mmHg in patients at risk of or with established coronary artery disease and 130/80 mmHg in diabetics. The cholesterol target is either total cholesterol of <5.0 mmol/L (LDL-cholesterol <3 mmol/L) or a reduction of 30% (whichever is greater).

Angina

The diagnosis of angina (see also p. 675 and Table 14.27) is largely based on the clinical history. The chest pain is generally described as ‘heavy’, ‘tight’ or ‘gripping’. Typically, the pain is central/retrosternal and may radiate to the jaw and/or arms. Angina can range from a mild ache to a most severe pain that provokes sweating and fear. There may be associated breathlessness.

Table 14.27 Canadian cardiovascular society functional classification of angina

Class I	No angina with ordinary activity. Angina with strenuous activity
Class II	Angina during ordinary activity, e.g. walking up hills, walking rapidly upstairs, with mild limitation of activities
Class III	Angina with low levels of activity, e.g. walking 50–100 yards on the flat, walking up one flight of stairs, with marked restriction of activities
Class IV	Angina at rest or with any level of exercise

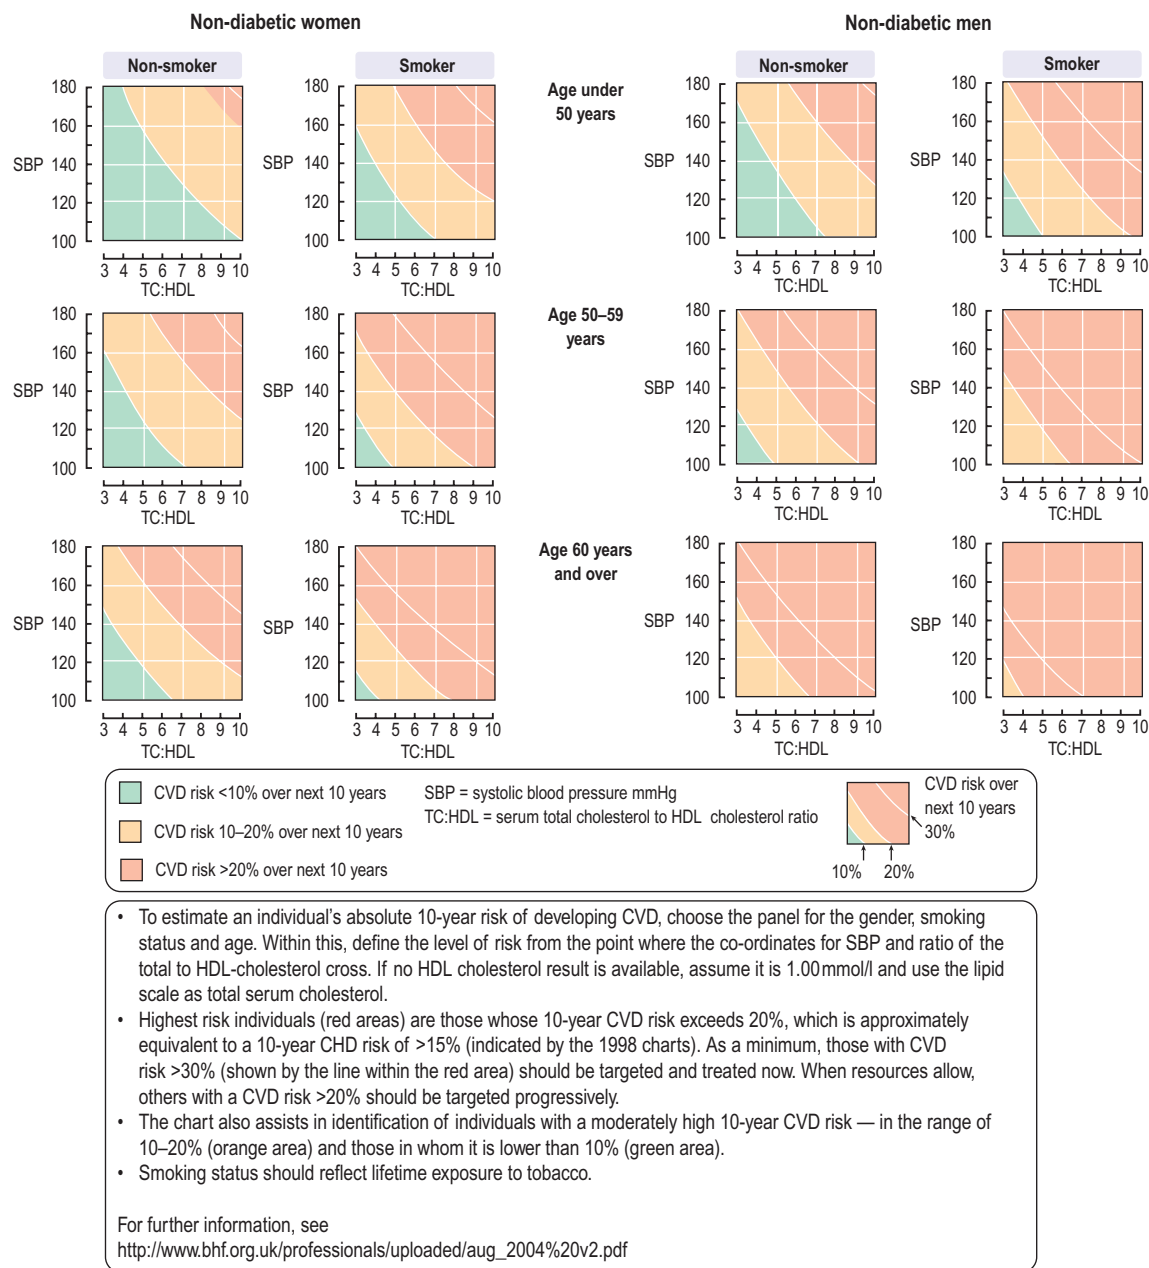

Figure 14.61 Cardiovascular risk prediction charts. (Cardiovascular risk prediction charts reproduced with permission from the University of Manchester, Department of Medical Illustration.)

The Health Survey for England 2006 reported a prevalence of angina of 14.2% in men aged 65–74 years and 8.3% in women aged 65–74 years old. In the UK, an estimated 2 million people over the age of 35 years have had angina.

Classical or exertional angina pectoris is characterized by:

- constricting discomfort in the front of the chest, arms, neck, jaw;
- provoked by physical exertion, especially after meals and in cold, windy weather or by anger or excitement and
- relieved (usually within minutes) with rest or glyceryl trinitrate. Occasionally, it disappears with continued exertion ('walking through the pain').

Typical angina has all three features, atypical angina two out of the three, and non-anginal chest pain one or less of these features.

Angina is stable when it is not a new symptom and when there is no change in the frequency or severity of attacks.

Unstable angina refers to angina of recent onset (<24 h) or a deterioration in previous stable angina with symptoms frequently occurring at rest, i.e. acute coronary syndrome (p. 730).

Refractory angina refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.

Variant (Prinzmetal's) angina refers to an angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women.

SIGNIFICANT WEBSITE

NICE clinical guideline 95, 'Chest pain of recent onset': <http://www.nice.org.uk/nicemedia/live/12947/47938/47938.pdf>

Characteristically, there is ST segment elevation on the ECG during the pain. Specialist investigation using provocation tests (e.g. hyperventilation, cold-pressor testing or ergometrine challenge) may be required to establish the diagnosis.

Cardiac syndrome X refers to those patients with a good history of angina, a positive exercise test and angiographically normal coronary arteries. They form a heterogeneous group, and the syndrome is much more common in women than in men. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress. See Table 14.27 for the Canadian Cardiovascular Society Functional Classification of Angina.

Examination

There are usually no abnormal findings in angina, although occasionally a fourth heart sound may be heard. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g. lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e. slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause for the angina. The blood pressure should be taken to identify co-existent hypertension.

Diagnosis and investigations for angina

Patients presenting with chest pain should have a 12-lead ECG performed to exclude an acute coronary syndrome. In many patients the ECG is normal between attacks although evidence of old myocardial infarction (e.g. pathological Q waves), left ventricular hypertrophy or left bundle branch block may be present. During an attack, transient ST depression, T wave inversion or other changes of the shape of the T wave may appear.

The diagnosis of stable angina can be made on clinical assessment alone OR by clinical assessment combined with anatomical (cardiac catheterization or CT coronary angiography) or functional imaging (SPECT, stress-echocardiography, stress-magnetic resonance imaging).

UK NICE guidance recommends assessing the likelihood of coronary artery disease in patients without known coronary artery disease who present with typical angina, atypical angina, or non-anginal chest pain (Table 14.28).

- Patients with *non-anginal chest pain* (more likely if the pain is continuous, is unrelated to exertion, is

exacerbated by respiration, is associated with dizziness, palpitations or difficulty in swallowing) should have alternate diagnoses considered and be investigated appropriately.

- Patients with *typical angina and a risk of disease of >90%* do not need further diagnostic investigation and should be managed for stable angina.
- Patients with *typical or atypical angina and a risk of disease of 61–90%* should have cardiac catheterization if appropriate.
- Patients with *typical or atypical angina and a risk of disease of 30–60%* should be referred for functional testing (SPECT, stress-echocardiography, stress-magnetic resonance imaging).
- Patients with *typical or atypical angina and a risk of disease of 10–29%* should be referred for CT coronary angiography. If CT calcium score is zero then angina is unlikely and other causes of chest pain should be sought (although young patients may have non-calcified plaque and CT angiography may be appropriate if symptomatic). If CT calcium score is 1–400, proceed to CT angiography but if the score is >400, invasive coronary angiography or functional imaging would be appropriate.
- If stable angina cannot be diagnosed in patients with known coronary artery disease then functional assessment would be appropriate.

NICE does *not* recommend exercise ECG as a diagnostic test in patients with chest pain symptoms although it has been present in the ESC guidelines from 2006. Using ST depression of <0.1 mV or 1 mm as a positive result, exercise ECG has a reported sensitivity of 67% and specificity of 72% for the detection of significant coronary disease in patients without prior myocardial infarction although interpretation of the findings is dependent on the prevalence of disease in the population and their presenting symptoms.

Management of stable angina

Patients should be informed as to the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Underlying problems, such as anaemia or hyperthyroidism, should be treated. Management of co-existent conditions, such as diabetes and hypertension, should be optimized. Risk factors should be evaluated and steps made to correct them where possible; e.g. smoking must be stopped, hypercholesterolaemia should be identified and treated (see below), weight loss, where appropriate, and regular exercise should be encouraged. The stable angina

Table 14.28 Likelihood of coronary artery disease in relation to type of presentation, age and risk: data are percentage of people

	Non-anginal chest pain				Atypical angina				Typical angina			
	Men		Women		Men		Women		Men		Women	
Age	Lo	Hi	Lo	Hi	Lo	Hi	Lo	Hi	Lo	Hi	Lo	Hi
35	3	35	1	19	8	59	2	39	30	88	10	78
45	9	47	2	22	21	70	5	43	51	92	20	79
55	23	59	4	25	45	79	10	47	80	95	38	82
65	49	69	9	29	71	86	20	51	93	97	56	84

Men >70 years with atypical or typical angina: assume risk >90%.
 Women >70 years: assume risk 61–90% unless high risk and typical angina (risk >90%).
 Hi, high risk – diabetes, smoking, hyperlipidaemia (total cholesterol >6.47 mmol/L); Lo, low risk – none of the above.
 Resting ECG abnormalities (ST-T changes, Q waves, LBBB) increases likelihood.

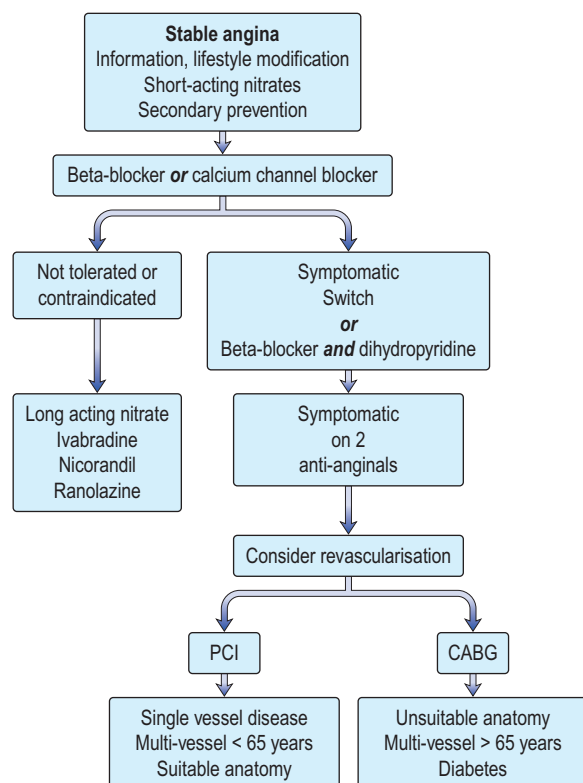

Figure 14.62 Algorithm for management of patients with stable angina. CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention. (From NICE draft guideline: <http://www.nice.org.uk/nicemedia/live/11878/52141/52141.pdf>.)

algorithm in Figure 14.62 should be used to guide initial patient management, as well as Table 14.29.

Low-dose aspirin is indicated. Symptomatic treatment should be started with the vasodilator sublingual or buccal nitrate to relieve acute episodes. Prophylaxis should be started with either a beta-adrenoceptor antagonist (e.g. atenolol) OR calcium channel receptor antagonist (e.g. diltiazem). If patients remain symptomatic then a beta-blocker can be combined with a dihydropyridine calcium channel receptor antagonist (e.g. amlodipine). Patients intolerant of beta-blockers and/or calcium channel blockers are treated with long-acting nitrates (e.g. isosorbide mononitrate) or I_f current inhibitor ivabradine or potassium channel activator nicorandil or sodium channel inhibitor ranolazine.

The Courage Trial published in April 2007 randomized patients with stable but significant coronary artery disease and inducible ischaemia to percutaneous coronary intervention with stenting ($n=1149$) or optimal medical therapy ($n=1138$). The primary composite outcome (all-cause death and non-fatal myocardial infarction) occurred in 211 (18.3%) of the PCI patients and 202 (17.8%) of the medically treated patients. This supports an initial strategy of optimal medical therapy in patients with stable angina symptoms although revascularization should be used in patients who remain symptomatic despite two anti-anginals.

Revascularization

Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) is the process of dilating a coronary artery stenosis using an inflatable balloon and metallic stent introduced into the arterial circulation via

the femoral, radial or brachial artery (Fig. 14.63). A discrete, soft lesion in a straight vessel without involving a bifurcation has the best outcome. Unfavourable lesions are occluded vessels, stenoses that are calcified, tortuous, long, or involve a bifurcation. Complications of the procedure include bleeding, haematoma, dissection and pseudoaneurysm from the arterial puncture site although the use of the radial artery may reduce the risks. Serious complications include acute myocardial infarction (2%), stroke (0.4%) and death (1%). Thrombotic complications are reduced with the use of heparin or the direct thrombin inhibitor *bivalirudin* together with the antiplatelet agents, aspirin and the thienopyridine *clopidogrel*. In very high-risk acute coronary syndrome or diabetic patients the antiplatelet GPIIb/IIIa antagonists (tirofiban, eptifibatide and abciximab) are also used. Reductions in the need for repeat revascularization have been seen with the introduction of coated stents lined with substances that reduce coronary artery restenosis. The *Cypher* stent contains sirolimus, which is an immunosuppressant agent that reduces cellular proliferation; everolimus is a derivative of sirolimus which is used in the *Xience V* stent. The *Taxus* stent contains paclitaxel, which is a mitotic inhibitor drug that inhibits neointima formation. Some concerns have been raised about late-stent thrombosis (>6 months post-insertion) in patients with drug-eluting stents leading to acute myocardial infarction and frequently death. It has been suggested that inadequate endothelialization of the stent leads to exposure of thrombus stimulating surface when the patient discontinues clopidogrel therapy, leading to recommendations that patients take prolonged dual therapy (aspirin and clopidogrel) and avoid discontinuing therapy within 6–12 months of implantation.

Coronary artery bypass grafting

With coronary artery bypass grafting (CABG) autologous veins or arteries are anastomosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (Fig. 14.64). Improved graft survival can be obtained with *in situ* internal mammary and gastroepiploic arteries grafted onto the stenosed coronary artery. Three major randomized controlled trials compared CABG with medical therapy: the Coronary Artery Surgery Study (CASS); the Veterans Administration (VA) Cooperative Study and the European Coronary Surgery Study (ECSS). A meta-analysis has been performed that demonstrated that compared to medical therapy, CABG significantly improved angina symptoms, exercise capacity and reduced the need for antianginal therapy. Operative mortality is well below 1% in patients with normal left ventricular function. Perioperative strokes occur in up to 2% of cases, and more subtle neurological deficits are common. Off-pump coronary surgery is now performed; results show that it is as safe as on-pump surgery and causes less myocardial damage, but the graft patency rate is lower. Minimally invasive operative procedures for bypass grafting ('MIDCAB') are being developed, including laparoscopic approaches, and may be of use in certain subgroups of patients (e.g. previous CABG and those with co-existent medical conditions which would increase the operative risks of 'full' CABG).

CABG versus PCI

Comparative trials between CABG and PCI have now been performed. All demonstrate a higher need for repeat revascularization with PCI than with CABG. In the ERACI II study, PCI patients had fewer major adverse events initially and better 18-month survival than the CABG group. The SoS Trial

reported a 2-year incidence of death or Q wave myocardial infarction of 9% in PCI versus 10% in CABG patients but fewer deaths in with CAGB (2% vs 5%). The SYNTAX study compared PCI with drug-eluting stents with CABG in patients with three-vessel disease and/or left main stem disease. The primary end-point (all cause death, stroke, myocardial infarction or repeat revascularization) occurred in more PCI patients. Although the draft guidance of stable angina from NICE recommends PCI for young patients with single or multi-vessel disease (and no diabetes), the European Society of Cardiology has recommended PCI ONLY in cases of single or double vessel disease NOT involving the proximal left anterior descending artery.

Patients with intractable angina

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization. These patients need a pain management programme.

Table 14.29 Pharmacological therapy in stable angina

Drug	Dose	Indications/mechanism of action/cautions
Vasodilator		
Glyceryl trinitrate	0.3–1.0 mg sublingual 2.0–3.0 mg buccal	Prophylaxis and treatment of angina – rapid onset Repeat after 5 min if symptomatic Vasodilatation (causes headache and flushing)
Isosorbide mononitrate	10–60 mg ×2 daily (slow release preparations are available)	Prophylaxis of angina Side-effects – headache and flushing Contraindicated with phosphodiesterase type-5 inhibitors
Beta-blocker		
Atenolol	25–100 mg daily	Inhibit beta-adrenoceptors, reduce heart rate and BP, reduce myocardial oxygen consumption
Bisoprolol	2.5–10 mg daily	Caution – COPD, acute heart failure, AV conduction
Metoprolol	25–100 mg ×2 or 3 daily	Side-effects – fatigue, peripheral vasoconstriction (cold peripheries), erectile dysfunction, bronchospasm
Calcium channel blockers		
Verapamil (<i>phenylalkylamines</i>)	80–120 mg ×3 daily (or 240–480 mg daily slow release)	Inhibit calcium channels in myocardium, cardiac conductive tissue and vascular smooth muscle
Diltiazem (<i>benzothiapines</i>)	60–120 mg ×3 daily (longer acting preparations are available)	Diltiazem and verapamil – contraindicated in severe bradycardia, left ventricular failure with pulmonary congestion, second- or third-degree AV block
Amlodipine (<i>dihydropyridines</i>)	5–10 mg daily	Side-effects – constipation (verapamil), ankle oedema (amlodipine, diltiazem), reflex tachycardia (amlodipine)
Second-line anti-anginal drugs		
Ivabradine	2.5–7.5 mg ×2 daily	Inhibits the pacemaker I_f current in the SA node Use in sinus rhythm ± beta-blocker Side-effects – bradycardia, phosphenes, Contraindications: sick-sinus syndrome, AV block
Nicorandil	5–30 mg ×2 daily	Activates ATP-sensitive potassium channels and has nitrate properties – peripheral and coronary vasodilatation Use as adjunctive therapy
Ranolazine	375–750 mg ×2 daily	Side-effects – headache, flushing, oral ulceration May inhibit late sodium channels in cardiac cells Use as adjunctive therapy Metabolized by cytochrome P450 3A4 Side-effects – constipation, dizziness, lengthens QT
Secondary prevention		
Aspirin	75 mg daily	Antiplatelet Side effects – gastrointestinal bleeding
Angiotensin-converting enzyme inhibitor	Variable	Indicated if treating other condition, e.g. hypertension, heart failure, chronic kidney disease
Statins	Variable	Use to reduce total cholesterol to below 4 mmol/L and LDL cholesterol to below 2 mmol/L

Acute coronary syndromes

Acute coronary syndromes (ACS) include:

- **ST-elevation myocardial infarction (STEMI)**
- **Non-ST-elevation myocardial infarction (NSTEMI)**
- **Unstable angina (UA).**

The difference between UA and NSTEMI is that in the latter there is occluding thrombus, which leads to myocardial necrosis and a rise in serum troponins or CK-MB. Myocardial infarction (MI) occurs when cardiac myocytes die due to myocardial ischaemia, and can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers – troponin I and T, CK-MB. There are three types of MIs:

- **Type 1** – spontaneous MI with ischaemia due to a primary coronary event, e.g. plaque erosion/rupture, fissuring or dissection

- **Type 2** – MI secondary to ischaemia due to increased oxygen demand or decreased supply, such as coronary spasm, coronary embolism, anaemia, arrhythmias, hypertension, or hypotension
- **Type 3,4,5** – diagnosis of MI in sudden cardiac death, after percutaneous coronary intervention (PCI) and after coronary artery bypass graft (CABG), respectively.

Pathophysiology

The common mechanism to all ACS is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin fibrous cap are associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane A_2 , results in myocardial ischaemia due to reduction of coronary blood flow.

Box 14.1 Relationship between troponin I and risk of death in patients with acute coronary syndrome

Serum troponin levels (ng/mL)	Mortality at 42 days (% of patients)
0 to <0.4	1.0
0.4 to <1.0	1.7
1.0 to <2.0	3.4
2.0 to <5.0	3.7
5.0 to <9.0	6.0
>9.0	7.5

(Adapted from Antman et al. Cardiac-specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. New England Journal of Medicine 1996; 335: 1342–1349.)

Diagnosis

Clinical presentation

Patients with an ACS may complain of a new onset of *chest pain*, chest pain at rest, or a deterioration of pre-existing angina. However, some patients present with atypical features including indigestion, pleuritic chest pain or dyspnoea. Physical examination can detect alternative diagnoses such as aortic dissection, pulmonary embolism or peptic ulceration. In addition it can also detect adverse clinical signs such as hypotension, basal crackles, fourth heart sounds and cardiac murmurs.

Electrocardiogram

Although the 12-lead ECG may be normal in patients with an ACS, ST depression and T wave inversion are highly suggestive for an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain, and continuous ST-segment monitoring is recommended. With a STEMI, complete occlusion of a coronary vessel will result in persistent ST-elevation or left bundle branch block pattern, although transient ST elevation is seen with coronary vasospasm or Prinzmetal's angina.

Biochemical markers

- The **cardiac troponin** complex is made up of three distinct proteins (I, T and C) that are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. Troponin T attaches the complex to tropomyosin, troponin C binds calcium during excitation-contraction coupling, and troponin I inhibits the myosin binding site on the actin. The cardiac troponins are not detectable in normal people and so monoclonal antibody tests to cardiac-specific troponin I and cardiac-specific troponin T are highly sensitive markers of myocyte necrosis. If the initial troponin assay is negative, then it should be repeated 6–12 h after admission. The troponin assay has prognostic information, i.e. a high serum troponin level has an increased mortality risk in ACS (Box 14.1), and defines which patients may benefit from aggressive medical therapy and early coronary revascularization.
- The measurement of the **creatinine-kinase-MB** level was, until recently, the standard marker for myocyte death used in ACS. However, the presence of low levels of CK-MB in the serum of normal individuals and in patients with significant skeletal muscle damage, has limited its accuracy. It can be used to determine reinfarction as levels drop back to normal after 36–72 hours.
- Myoglobin** may be useful for a rapid diagnosis of an ACS as the levels become elevated very early in the

Table 14.30 The TIMI risk score in acute coronary syndrome (NSTEMI/UA)

Risk factor	Score	
Age >65	1	
More than three coronary artery disease risk factors – hypertension, hyperlipidaemia, family history, diabetes, smoking	1	
Known coronary artery disease (coronary angiography stenosis >50%)	1	
Aspirin use in the last 7 days	1	
Severe angina (more than two episodes of rest pain in 24 h)	1	
ST deviation on ECG (horizontal ST depression or transient ST elevation >1 mm)	1	
Elevated cardiac markers (CK-MB or troponin)	1	
Total score	Rate of death/MI in 14 days (%)	Rate of death/MI/urgent revascularization (%)
0–1	3	4.75
2	3	8.3
3	5	13.2
4	7	19.9
5	12	26.2
6–7	19	40.9

time course of an MI, but because of the presence of myoglobin in skeletal muscle the test has poor specificity for ACS.

NSTEMI and unstable angina

Risk stratification in NSTEMI and unstable angina

Initial risk in ACS is determined by complications of the acute thrombosis. This may produce recurrent myocardial ischaemia, marked ST depression, dynamic ST changes, a raised troponin level and be demonstrated with coronary angiography.

Long-term risks defined by clinical risk factors; age, prior myocardial infarction or bypass surgery, diabetes or heart failure. Biological markers, such as C-reactive protein, fibrinogen, brain natriuretic peptide, modified albumin and serum creatinine, can be used to further stratify patient risk. Left ventricular dysfunction and the presence of left main or triple vessel disease significantly increase the future cardiovascular risk. Both the Thrombolysis In Myocardial Infarction (TIMI) score and the Global Registry of Acute Coronary Events (GRACE) prediction score can be used in patients with ACS to define risk. TIMI is shown in Table 14.30. The GRACE score is based on age, heart rate, systolic blood pressure, serum creatinine and the Killip score.

Investigation and treatment of NSTEMI and UA

All patients require immediate management of their chest pain as outlined on page 738 and in Table 14.31.

High-risk patients for progression to myocardial infarction or death require urgent coronary angiography. These patients include those with persistent or recurrent angina with ST changes ≥ 2 mm or deep negative T wave changes, clinical signs of heart failure or haemodynamic instability, life-threatening arrhythmias (VF, VT).

Patients with *immediate* or *high-risk* TIMI or GRACE scores, elevated troponins, dynamic ST or T wave changes, diabetes mellitus, renal dysfunction, reduced left ventricular function, early post-infarction angina, previous myocardial infarction, PCI within 6 months, or previous CABG, should have early (<72 h) coronary angiography and interventions.

Table 14.31 Pharmacological therapy in acute coronary syndrome

Drug	Notes	
Myocardial oxygenation		
Oxygen	35–50%	Check ABG in severe COPD
Antiplatelet		
Aspirin	150–300 mg chewable or soluble aspirin, then 75–10 mg orally daily	Caution if active peptic ulceration
Clopidogrel	300 mg orally loading dose, then 75 mg orally daily	Caution: increased risk of bleeding, avoid if CABG planned
Prasugrel	60 mg oral loading dose, then 10 mg orally daily (5 mg daily if <60 kg or >75 years old)	
Ticagrelor	Initially 180 mg, then 90 mg x2 daily	Risk of bleeding
Antithrombin		
Heparin	5000 units i.v. bolus, then 0.25 units/kg per hour	Measure anticoagulant effect with APTT at 6 h
Low-molecular-weight heparins, e.g. enoxaparin	1 mg/kg s.c. x2 daily	
Bivalirudin	750 µg/kg i.v. bolus, then 1.75 mg/kg per hour for 4 h post PCI	Risk of bleeding
Fondaparinux	2.5 mg SC daily, for up to 8 days	
Rivaroxaban	Oral 2.5–10 mg daily	
Glycoprotein IIB/IIIA inhibitors		
Abciximab	0.25 mg/kg i.v. bolus, then 0.125 µg/kg per min up to 10 µg/min i.v. x12 h	Indicated if coronary intervention likely within 24 h
Eptifibatide	180 µg/kg i.v. bolus, then 2 µg/kg per min x72 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Tirofiban	0.4 µg/kg per min for 30 min, then 0.1 µg/kg per min x48–108 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Analgesia		
Diamorphine or morphine	2.5–5.0 mg i.v.	Prescribe with antiemetic, e.g. metoclopramide 10 mg i.v.
Myocardial energy consumption		
Atenolol	5 mg i.v. repeated after 15 min, then 25–50 mg orally daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Metoprolol	5 mg i.v. repeated to a maximum of 15 mg, then 25–50 mg orally x2 daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Coronary vasodilation		
Glyceryl trinitrate	2–10 mg/h i.v./buccal/sublingual	Maintain systolic BP >90 mmHg
Plaque stabilization/ventricular remodeling		
HMG-CoA reductase inhibitors (statins)		Combine with dietary advice and modification
Simvastatin	20–40 mg orally	
Pravastatin	20–40 mg orally	Monitor renal function
Atorvastatin	80 mg orally	
ACE inhibitors		
Ramipril	2.5–10 mg orally	
Lisinopril	5–10 mg orally	

Low-risk patients can be managed with oral aspirin, clopidogrel, beta-blockers and nitrates. These include patients with no recurrence of chest pain during observation, no signs of heart failure, normal ECG or minor T wave changes on arrival and at 6–12 h, normal troponins on the initial assays and at 6–12 h post admission. An exercise test should be performed – a negative result has a good prognosis and an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. left ventricular hypertrophy or LBBB), then dobutamine stress echocardiography or myocardial perfusion scintigraphy are recommended. These tests are often used as the first line investigation.

Antiplatelet agents

The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes

the circulating platelets to ADP (adenosine diphosphate), thromboxane A₂ (TxA₂), epinephrine (adrenaline), thrombin and collagen tissue factor. This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation stimulates the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface. These receptors bridge fibrinogen between adjacent platelets, causing platelet aggregates (Fig. 8.41).

Aspirin blocks the formation of thromboxane A₂ and so prevents platelet aggregation. In ACS patients, 75–150 mg aspirin reduced the relative risk of death or myocardial infarction by about 35–50%. Ticagrelor, a nucleoside analogue, is used in combination with aspirin for the acute coronary syndrome.

Clopidogrel is a thienopyridine that inhibits ADP-dependent activation of the GPIIb/IIIa complex that allows platelet aggregates to form. In the CURE study of 12562

ACS patients, 9 months of 75 mg clopidogrel reduced the primary end-point of cardiovascular death, myocardial infarction, or stroke from 11.4% to 9.3% ($p < 0.0001$), compared with placebo. However, *clopidogrel* is a pro-drug requiring conversion by hepatic cytochrome P450 enzymes to an active moiety that binds irreversibly to the P2Y₁₂ receptor on platelet membranes and inhibits the ADP-dependent pathway of platelet activation. Proton-pump inhibitors, e.g. *omeprazole*, and genetic variation in the cytochrome P450 enzymes may theoretically reduce the effectiveness of clopidogrel. This has not been a problem in clinical practice. The TRITON-TIMI 38 study found that the thienopyridine *prasugrel* reduced ischemic events (12.1% with *clopidogrel* and 9.9% with *prasugrel*) but increased the risk of major bleeding (1.8% with *clopidogrel* and 2.4% with *prasugrel*).

Activated GP (glycoprotein) IIb/IIIa receptors on platelets bind to fibrinogen initiating platelet aggregation. Receptor antagonists have been developed that are powerful inhibitors of platelet aggregation. Abciximab is a monoclonal antibody that binds tightly and has a long half-life. Eptifibatide is a cyclic peptide that selectively inhibits GPIIb/IIIa receptors, but has a short half-life and wears off in 2–4 h. Tirofiban is a small non-peptide that rapidly blocks the GPIIb/IIIa receptors and is reversible in 4–6 h.

In the GUSTO-IV ACS study of 7800 patients, abciximab was administered but coronary intervention discouraged. At 30 days, 8.2% of abciximab patients and 8.0 % of placebo patients had reached the composite end-point of death or myocardial infarction. In the PRISM study of 3232 patients with angina, tirofiban reduced the 30-day death or myocardial infarction rate from 7.1% with placebo to 5.8%. Troponin-positive patients with diabetes scheduled to have coronary intervention benefit most from GPIIb/IIIa receptor antagonists.

Antithrombins

In ACS patients off aspirin, *unfractionated heparin (UFH)* produces a lower rate of refractory angina/myocardial infarction and death than placebo, and when used with aspirin reduces death and myocardial infarction from 10.3% to 7.9%. However, because of poor bioavailability and variable effects, frequent monitoring of APTT is necessary to ensure therapeutic levels. *Low-molecular-weight heparins* and in particular *enoxaparin* appear superior to UFH and can be given subcutaneously twice daily. Bivalirudin is a direct thrombin inhibitor that reversibly binds to thrombin and inhibits clot-bound thrombin. In the ACUTY trial, bivalirudin appeared as effective as heparin plus GPIIb/IIIa inhibitors in reducing ischaemic events in patients pretreated with a thienopyridine and undergoing diagnostic angiography or percutaneous intervention, but with less bleeding. *Fondaparinux* is a synthetic pentasaccharide that selectively binds to antithrombin, which inactivates factor Xa resulting in a strong inhibition of thrombin generation and clot formation. It does not inactivate thrombin and has no effect on platelets. The OASIS-5 trial evaluated the efficacy and safety of *fondaparinux* and *enoxaparin* in 20078 high-risk patients with unstable angina or myocardial infarction without ST-segment elevation. Thrombotic endpoints were similar with both agents but *fondaparinux* was associated with less bleeding end-points at 2.2% compared with 4.1% with *enoxaparin* patients.

Rivaroxaban, a factor Xa inhibitor, is effective in reducing the risk of further cardiac events but with a risk of bleeding.

Anti-ischaemia agents

In patients with no contraindications (asthma, AV-block, acute pulmonary oedema), beta-blockers are administered intravenously or orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will reduce the heart rate and blood pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50–60 b.p.m. In patients with ongoing angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilation. However, tolerance can become a problem and patients should be weaned off intravenous administration if symptoms resolve.

Plaque stabilization/remodelling

HMG-CoA reductase inhibitor drugs (statins) and ACE inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs whilst the patient is still in hospital increases the likelihood of patients receiving secondary drug therapy.

Coronary intervention

Coronary revascularization is recommended in high-risk patients with ACS. Coronary stenting may stabilize the disrupted coronary plaque; in the BENESTENT II trial it was demonstrated that stenting was superior to PTCA in reducing angiographic restenosis rates. Subgroup analysis of patients with unstable angina in the EPIC, EPILOG and CAPTURE trials confirmed the benefit of GPIIb/IIIa inhibitors at reducing the complication rate during PCI. The PCI-CURE study demonstrated that pretreatment with clopidogrel reduces the rate of cardiovascular death and MI. The current rate of CABG in ACS is low (5.4%). The mortality rates with CABG are greater in the high-risk group patients, particularly with a recent myocardial infarction. Single vessel lesions are usually treated with PCI, unless the anatomy is unfavourable. Conversely in patients with left main stem or triple vessel disease with impaired left ventricular function are best managed with surgery. Two studies have compared a conservative versus an invasive strategy in the modern era. In the FRISC-II study 2457 high-risk ACS patients were randomized to PTCA or CABG at 4 and 8 days, respectively, or a conservative approach with intervention only for severe angina. Revascularization within 10 days was performed in 71% of the invasive arm versus 9% of the conservative arm. After 1 year, there was a significant reduction in total mortality (2.2% vs 3.9%) in the invasive arm, as well as a significant reduction in MI (8.6% vs 11.6%). In addition, the rate of angina or readmission was reduced by 50%. In the TACTICS study of 2220 high-risk ACS patients, similar findings were obtained with the rate of death or MI reduced from 9.5% to 7.3% by an invasive strategy. Patients with a troponin T >0.01 ng/mL obtained benefit, but not those who were troponin T negative.

ST elevation myocardial infarction (STEMI)

Myocardial infarction occurs when cardiac myocytes die due to prolonged myocardial ischaemia. The diagnosis can be made in patients with an appropriate clinical history together with findings from repeated 12-lead ECGs and elevated biochemical markers – troponin I and T, CK-MB.

Pathophysiology

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery leading

to myocardial necrosis within 15–30 minutes. The subendocardial myocardium is initially affected but with continued ischaemia the infarct zone extends through to the subepicardial myocardium, producing a transmural Q wave myocardial infarction. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity.

The 1-month mortality in patients with a myocardial infarction may be as high as 50% in the community, with 50% of deaths occurring in the first 2 hours of the event. In the pre-thrombolytic era the in-hospital mortality rate was nearly 20% but with modern therapy it may be as low as 6–7% at 1 month. Several risk factors can be identified that predict death rate at 30 days (TIMI STEMI score; Table 14.32).

Diagnosis

Symptoms and signs

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from a myocardial

infarction. The pain does not usually respond to sublingual GTN, and opiate analgesia is required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly elderly or diabetic patients, the symptoms may be atypical and include dyspnoea, fatigue, pre-syncope or syncope. Autonomic symptoms are common and on examination the patient is pale and clammy, with marked sweating. In addition, the pulse is thready with significant hypotension, bradycardia or tachycardia.

Electrocardiography

An ECG in patients with chest pain should be performed on admission to A&E. The baseline ECG is rarely normal, but if so should be repeated every 15 minutes, while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Table 14.33) are usually confined to the ECG leads that 'face' the infarction. The presence of new ST elevation (due to opening of the K^+ channels) ≥ 0.2 mV at the J-point in leads V_1 – V_3 , and ≥ 0.1 mV in other leads, suggests anterior MI (Fig. 14.65). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 14.66). Lateral MI produces changes in leads I, AVL and V_5 / V_6 . In patients with a posterior MI, there may be ST depression in leads V_1 – V_3 with a dominant R wave, and ST elevation in lead V_5 / V_6 . New LBBB or presumed new LBBB is compatible with coronary artery occlusion requiring urgent reperfusion therapy. The evolution of the ECG during the course of STEMI is illustrated in Figure 14.67.

Investigations

Blood samples should be taken for cardiac troponin I or T levels, although treatment should not be deferred until the

Figure 14.66 An acute inferior wall myocardial infarction shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III and AVF). The additional T wave inversion in V_4 and V_5 probably represents anterior wall ischaemia.

Figure 14.67 Electrocardiographic evolution of myocardial infarction (STEMI). After the first few minutes the T waves become tall, pointed and upright and there is ST segment elevation. After the first few hours the T waves invert, the R wave voltage is decreased and Q waves develop. After a few days the ST segment returns to normal. After weeks or months the T wave may return to upright but the Q wave remains.

results are available. Full blood count, serum electrolytes, glucose and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm a myocardial infarction, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses such as aortic dissection, pericarditis or pulmonary embolism.

Early medical management

Accident and emergency

Rapid triage for chest pain (Note: time is muscle):

- Aspirin 150–300 mg chewed and clopidogrel 300 mg oral gel
- Sublingual glyceryl trinitrate 0.3–1 mg. Repeat
- Oxygen – nasal cannula 2–4 L/min (Fig. 16.21) if hypoxia is present
- Brief history/risk factors. Examination
- Intravenous access + blood for markers (plus FBC, biochemistry, lipids, glucose)
- 12-lead ECG
- Intravenous opiate, e.g. diamorphine (or morphine) 2.5–5 mg + antiemetic, e.g. metoclopramide 10 mg
- Beta-blocker (if no contraindication) for ongoing chest pain, hypertension, tachycardia
- If primary PCI available (see p. 738), give GP IIb/IIIa inhibitor. Alternatively, give thrombolysis (see below).

Pre-hospital treatment, including thrombolysis, can be given by trained healthcare professionals under strict guidelines.

Percutaneous coronary intervention (PCI)

PCI performed within 90 minutes is the preferred reperfusion therapy in interventional cardiology centres that have the expertise available. In the PAMI (Primary Angioplasty in Myocardial Infarction) trial, patients with a myocardial infarction who presented within 12 hours of the onset of STEMI were randomized to primary PTCA or t-PA followed by conservative care. At 2-year follow-up the primary PTCA group had less recurrent ischaemia, lower re-intervention rates and reduced hospital readmission rates. Primary PTCA produced a combined end-point of death or re-infarction of 14.9% compared to 23% for t-PA. PCI with thrombus aspiration has recently been shown to result in better reperfusion and clinical outcomes.

The DANAMI 2 study investigated if rapid transfer of patients with STEMI for primary angioplasty in an interventional centre was superior to thrombolysis. Patients within 12 hours of a high-risk STEMI (>4 mm elevation) received front-loaded t-PA, primary angioplasty at a local centre, or primary angioplasty at an interventional centre after transfer.

Primary PCI significantly reduced the death rate in both local and transferred patients as compared to thrombolytic therapy (8.0% vs 13.7%). The majority of the benefits with primary PCI are obtained by a reduction in recurrent myocardial infarction.

Coronary stenting in primary PCI reduces the need for repeat target vessel revascularization but did not appear to reduce mortality rates. However, one study using drug-eluting stents showed a decreased 2-year mortality rate.

The use of abciximab in STEMI patients undergoing primary angioplasty reduces immediate outcome (death, myocardial infarction, urgent revascularization), but this benefit is minimal by 6 months.

PCI following thrombolysis was initially discouraged but a trial has suggested that it is safe and improves the 1-year clinical outcome. Randomized trials have compared a strategy of thrombolysis (in hospitals without PCI capability) versus transfer to a PCI centre and have demonstrated a significant reduction in the combined end-point of death, reinfarction and stroke (although with a non-significant reduction in mortality) with transfer. The strategy of transfer for primary PCI is appropriate if the intervention can be performed within 90 minutes of presentation and this is now optimal therapy.

Fibrinolysis

Fibrinolytic agents (p. 426) enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. Fibrinolysis is still used if PCI is unavailable.

A meta-analysis of fibrinolytics (FTT), fibrinolysis within 6 h of STEMI or LBBB MI, prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours, 20 in every 1000 deaths were prevented. After 12 hours, the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes.

Prompt reperfusion therapy (door to needle time <30 min) will reduce the death rate following myocardial infarction. Double bolus r-PA (reteplase) and single bolus TNK-t-PA (tenecteplase) facilitate rapid administration of fibrinolytic therapy and can be used for pre-hospital thrombolysis. In patients who fail to reperfuse by 60–90 minutes, as demonstrated by 50% resolution of the ST segment elevation, rethrombolysis or referral for rescue coronary angioplasty is recommended.

Aspirin therapy should be prescribed with fibrinolysis, but there is little additional benefit in combining clopidogrel or abciximab therapy in patients with STEMI/new LBBB. Heparin is recommended with t-PA or tenecteplase, but not with streptokinase. Enoxaparin (low-molecular-weight heparin) appears to be superior to unfractionated i.v. heparin in patients receiving TNK-t-PA, with less reocclusion and better late patency (ASSENT 3).

The contraindications to thrombolysis are provided in Table 14.34.

Coronary artery bypass surgery

Cardiac surgery is usually reserved for the complications of myocardial infarction, such as ventricular septal defect or mitral regurgitation.

Complications of myocardial infarction

Heart failure

Cardiac failure post STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate (see Table 14.36). The Killip classification is used to assess patients with heart failure post-MI:

Table 14.34 Contraindications to thrombolysis

Absolute contraindications

Haemorrhagic stroke or stroke of unknown origin at any time
Ischaemic stroke in preceding 6 months
Central nervous system damage or neoplasms
Recent major trauma/surgery/head injury (within preceding 3 weeks)
Gastrointestinal bleeding within the last month
Known bleeding disorder – aortic dissection

Relative contraindications

Transient ischaemic attack in preceding 6 months
Oral anticoagulant therapy
Pregnancy or within 1 week postpartum
Non-compressible punctures
Traumatic resuscitation
Refractory hypertension (systolic blood pressure >180 mmHg)
Advanced liver disease
Infective endocarditis

- **Killip I** – no crackles and no third heart sound
- **Killip II** – crackles in <50% of the lung fields or a third heart sound
- **Killip III** – crackles in >50% of the lung fields
- **Killip IV** – cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40–80 mg i.v., with GTN administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring. ACE inhibitors can be given in <24–48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan–Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes such as dopamine or dobutamine are used in patients with severe heart failure. If the patient is in cardiogenic shock, then revascularization ± intra-aortic balloon pump insertion may be required.

Myocardial rupture and aneurysmal dilatation

Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis followed by the surgical repair of the rupture. Aneurysmal dilatation of the infarcted myocardium (Fig. 14.68) is a late complication that may require surgical repair.

Ventricular septal defect (VSD)

A VSD may occur in 1–2.0% of patients with STEMI, and may be associated with delayed or failed fibrinolysis. However, mortality is very high with a 12-month unoperative mortality of 92%. An intra-aortic balloon pump (IABP) and coronary angiography may allow for patient optimization prior to surgery. A post-infarct VSD is demonstrated in Figure 14.69.

Mitral regurgitation

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible for the mitral regurgitation, and a transoesophageal echocardiogram (TOE) may be necessary to confirm the aetiology:

- Severe left ventricular dysfunction and dilatation, causing annular dilatation of the valve and subsequent regurgitation
- Myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention

Figure 14.69 Post-infarct ventricular septal defect.

- Myocardial infarction of the papillary muscles, producing sudden severe pulmonary oedema and cardiogenic shock (IABP, coronary angiography and early surgery may improve patient survival).

Cardiac arrhythmias

Ventricular tachycardia and *ventricular fibrillation* are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia should be treated with intravenous beta-blockers (metoprolol 5 mg, esmolol 50–200 µg/kg per min), lidocaine 50–100 mg, or amiodarone 900–1200 mg/24 hours. If the patient is hypotensive, synchronized cardioversion may be performed. Ensure that the serum potassium is above 4.5 mmol/L. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 min i.v.

Atrial fibrillation occurs frequently and treatment with beta-blockers and digoxin may be required. Cardioversion is possible but relapse is frequent.

Bradycardia can be treated initially with i.v. atropine 0.5 mg repeated up to six times in 4 hours. Temporary transcutaneous or transvenous pacemaker insertion may be required in patients with symptomatic heart block.

Conduction disturbances

These are common following MI. AV block may occur during acute MI, especially of the inferior wall (the right coronary

artery usually supplies the SA and AV nodes). Heart block, when associated with haemodynamic compromise, may need treatment with atropine or a temporary pacemaker. Such blocks may last for only a few minutes, but frequently continue for several days. Permanent pacing may need to be considered if heart block persists for over 2 weeks.

Post-MI pericarditis and Dressler's syndrome

See section entitled 'Pericardial disease', below.

Post-ACS lifestyle modification

After recovery from an ACS patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to the patients' requirements. An exercise programme forms part of the rehabilitation.

- Patients should be encouraged to eat a Mediterranean-style diet and to consume >7 g of omega-3 fatty acids/week from oily fish or >1 g daily of omega-3-acid ethyl esters.
- Patients should maintain alcohol consumption within safe limits (≤21 units/week for men or <14 units for women) and avoid binge drinking.
- Patients should be physically active for 20–30 min/day.
- Patients should stop smoking.
- Overweight and obese patients should be offered advice and support to achieve and maintain a healthy weight.
- Patients with hypertension should be treated to <140/90 or <130/80 if chronic kidney disease or diabetes.
- Patients with diabetes should be treated to maintain HbA_{1c} <7%.

Post-ACS drug therapy and assessment

Extensive clinical trial evidence has been gathered in post-myocardial infarction patients, demonstrating that a range of pharmaceuticals are advantageous in reducing mortality over the following years. Therefore, post-MI most patients should be taking most of the following medications:

- Aspirin 75–100 mg/day
- A beta-blocker to maintain heart rate <60 b.p.m., e.g. metoprolol 50 mg twice daily
- ACE inhibitors, e.g. ramipril 2.5 mg twice daily, titrated to maximum tolerated or target dose (if intolerant of ACE inhibitors use ARB, e.g. valsartan 20 mg twice daily titrated to maximum tolerated or target dose)
- Statins, e.g. simvastatin 20–80 mg/day
- Clopidogrel 75 mg/day for 9–12 months should be added in moderate–high-risk patients with non-ST elevation acute coronary syndrome (NST-ACS)
- Aldosterone antagonist, e.g. eplerenone 25 mg/day, should be given in patients post-MI with clinical evidence of heart failure and reduced ejection fraction (renal function and potassium levels should be monitored).

VALVULAR HEART DISEASE

Mitral valve

The mitral valve consists of the fibrous annulus, anterior and posterior leaflets, chordae, tendinae and the papillary muscles (Fig. 14.70).

Mitral stenosis

The most common cause of mitral stenosis is rheumatic heart disease secondary to previous rheumatic fever due to infection with group A β -hemolytic streptococcus which in the developing world affects nearly 20 million people. The condition is more common in women than men. Inflammation leads to commissural fusion and a reduction in mitral valve orifice area leading to the characteristic doming pattern seen on echocardiography. Over many years the condition progresses to valve thickening, cusp fusion, calcium deposition, a severely narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes of mitral stenosis include:

- Lutembacher's syndrome, which is the combination of acquired mitral stenosis and an atrial septal defect
- a rare form of congenital mitral stenosis
- in the elderly, a syndrome similar to mitral stenosis, which develops because of calcification and fibrosis of the valve, valve ring and subvalvular apparatus (chordae tendineae)
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Figure 14.70 Mitral valve apparatus – parasternal long axis. Arrows, annulus; P, papillary muscle; T, chordae tendineae; L, leaflets.

Pathophysiology

When the normal valve orifice area of 4–6 cm² is reduced to <1 cm², severe mitral stenosis is present. In order that sufficient cardiac output will be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is followed by the development of pulmonary oedema particularly when the rhythm deteriorates to atrial fibrillation with tachycardia and loss of coordinated atrial contraction. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilatation and failure with subsequent tricuspid regurgitation.

Symptoms

Usually there are no symptoms until the valve orifice is moderately stenosed (i.e. has an area of 2 cm²). In Europe, this does not usually occur until several decades after the first attack of rheumatic fever, but children of 10–20 years of age in the Middle or Far East may have severe calcific mitral stenosis.

Because of pulmonary venous hypertension and recurrent bronchitis, progressively severe *dyspnoea* develops. A cough productive of blood-tinged, frothy sputum or frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to *right heart failure* and its symptoms of weakness, fatigue and abdominal or lower limb swelling.

The large left atrium favours *atrial fibrillation*, giving rise to symptoms such as palpitations. Atrial fibrillation may result in *systemic emboli*, most commonly to the cerebral vessels resulting in neurological sequelae, but mesenteric, renal and peripheral emboli are also seen.

Signs

See Clinical memo in Figure 14.71.

Face

Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral facies or malar flush. This is

Figure 14.71 Features associated with mitral regurgitation and mitral stenosis. A2, aortic component of the second heart sound; MDM, mid-diastolic murmur; OS, opening snap; P2, pulmonary component of the second heart sound (loud with pulmonary hypertension); PSA, presystolic accentuation; PSM, pansystolic murmur; S1, first heart sound; S2, second heart sound; S3, third heart sound.

a bilateral, cyanotic or dusky pink discoloration over the upper cheeks that is due to arteriovenous anastomoses and vascular stasis.

Pulse

Mitral stenosis may be associated with a small-volume pulse which is usually regular early on in the disease process when most patients are in sinus rhythm. However, as the severity of the disease progresses, many patients develop atrial fibrillation resulting in an irregularly irregular pulse. The development of atrial fibrillation in these patients often causes a dramatic clinical deterioration.

Jugular veins

If right heart failure develops, there is obvious distension of the jugular veins. If pulmonary hypertension or tricuspid stenosis is present, the 'a'-wave will be prominent provided that atrial fibrillation has not supervened.

Palpation

There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation

Auscultation (Fig. 14.71) reveals a loud first heart sound if the mitral valve is pliable, but it will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an 'opening snap' will be heard. This is followed by a low-pitched 'rumbling' mid-diastolic murmur best heard with the bell of the stethoscope held lightly at the apex with the patient lying on the left side. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation).

The severity of mitral stenosis is judged clinically on the basis of several criteria:

- The presence of pulmonary hypertension implies that mitral stenosis is severe. Pulmonary hypertension is recognized by a right ventricular heave, a loud pulmonary component of the second heart sound, eventually with signs of right-sided heart failure, such as oedema and hepatomegaly. Pulmonary hypertension results in pulmonary valvular regurgitation that causes an early diastolic murmur in the pulmonary area known as a Graham Steell murmur.
- The closeness of the opening snap to the second heart sound is proportional to the severity of mitral stenosis.
- The length of the mid-diastolic murmur is proportional to the severity.
- As the valve cusps become immobile, the loud first heart sound softens and the opening snap disappears. (For recordings of heart sounds, see online at Student Consult.) When pulmonary hypertension occurs, the pulmonary component of the second sound is increased in intensity and the mitral diastolic murmur may become quieter because of the reduction of cardiac output.

Investigations

Chest X-ray

The chest X-ray usually shows a generally small heart with an enlarged left atrium (Fig. 14.14). Pulmonary venous hypertension is usually also present. Late in the course of the disease a calcified mitral valve may be seen on a penetrated

or lateral view. The signs of pulmonary oedema or pulmonary hypertension may also be apparent when the disease is severe.

Electrocardiogram

In sinus rhythm the ECG shows a bifid P wave owing to delayed left atrial activation (Fig. 14.72). However, atrial fibrillation is frequently present. As the disease progresses, the ECG features of right ventricular hypertrophy (right axis deviation and perhaps tall R waves in lead V₁) may develop (Fig. 14.73).

Imaging

Echocardiogram (Fig. 14.74)

Transthoracic echocardiography should be used to determine left and right atrial and ventricular size and function. The severity of the mitral stenosis (Table 14.35) can be defined by planimetry of the mitral valve area on 2-dimensional echocardiography; with continuous wave (CW) Doppler use to measure the pressure half time (the time taken for the pressure to halve from the peak value) and mean pressure drop across the valve. The Wilkins score can be used to determine if the valve is suitable for percutaneous valvotomy. Continuous wave (CW) Doppler may also be used to estimate of pulmonary artery pressure through measurement of the degree of tricuspid regurgitation.

Figure 14.72 A bifid P wave as seen on the ECG in mitral stenosis (P mitrale). Also shown for comparison are other P wave abnormalities.

Figure 14.73 Severe mitral stenosis shown by a 12-lead ECG. Note the right axis deviation (frontal plane axis = +120°), the left atrial conduction abnormality (large terminal negative component of the P wave in V₁) and the right ventricular hypertrophy (R wave in V₁ and right axis deviation).

Table 14.35 Echocardiographic severity of mitral stenosis

	Normal	Mild	Moderate	Severe
Pressure half time (ms)	40–70	71–139	140–219	>219
Mean pressure drop (mmHg)		<5.0	5–10	>10
Valve area (cm ²)	4.0–6.0	1.6–2.0	1.0–1.5	<1.0
British Society of Echocardiography.				

Transoesophageal echocardiography (TOE) is performed to detect the presence of left atrial thrombus (p. 687) or prior to consideration of surgical or percutaneous intervention.

Cardiac magnetic resonance (CMR; see p. 688)

This can accurately show mitral valve anatomy although it is rarely used in mitral stenosis.

Cardiac catheterization

This is now seldom required and is only used if co-existing cardiac problems (e.g. mitral regurgitation or coronary artery disease) are suspected. Right heart catheterization may be required to determine pulmonary artery pressure in patients referred for valve intervention.

Treatment

Mild mitral stenosis may need no treatment other than prompt therapy of attacks of bronchitis. Infective endocarditis in pure mitral stenosis is uncommon. Early symptoms of mitral stenosis such as mild dyspnoea can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with digoxin and anticoagulation to prevent atrial thrombus and systemic embolization. If pulmonary hypertension develops or the symptoms of pulmonary congestion persist despite therapy, surgical relief of the mitral stenosis is advised. There are four operative measures.

Trans-septal balloon valvotomy

A catheter is introduced into the right atrium via the femoral vein under local anaesthesia in the cardiac catheter laboratory. The interatrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve, and then inflated briefly to split the valve commissures. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see below). This procedure is ideal for patients with pliable valves in whom there is little involvement of the subvalvular apparatus and in whom there is minimal mitral regurgitation. Contraindications include heavy calcification or more than mild mitral regurgitation and thrombus in the left atrium. Transoesophageal echocardiography must be performed prior to this technique in order to exclude left atrial thrombus.

Closed valvotomy

This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon's finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and eventually another operation may be necessary.

Open valvotomy

This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

Mitral valve replacement

Replacement of the mitral valve is necessary if:

- Mitral regurgitation is also present
- There is a badly diseased or badly calcified stenotic valve that cannot be reopened without producing significant regurgitation
- There is moderate or severe mitral stenosis and thrombus in the left atrium despite anticoagulation.

Artificial valves (see p. 750) may work successfully for >20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

Mitral regurgitation

Mitral regurgitation (MR) can occur due to abnormalities of the valve leaflets, the annulus, the chordae tendineae or papillary muscles, or the left ventricle. The most frequent causes of mitral regurgitation are degenerative (myxomatous) disease, ischemic heart disease, rheumatic heart disease, and infectious endocarditis. Mitral regurgitation is also seen in diseases of the myocardium (dilated and hypertrophic cardiomyopathy), rheumatic autoimmune diseases, e.g. systemic lupus erythematosus, collagen diseases, e.g. Marfan's and Ehlers–Danlos syndromes, and drugs including centrally acting appetite suppressants (fenfluramine) and dopamine agonists (cabergoline).

Pathophysiology

Regurgitation into the left atrium produces left atrial dilatation but little increase in left atrial pressure if the regurgitation is long-standing, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation the normal compliance of the left atrium does not allow much dilatation and the left atrial pressure rises. Thus, in acute mitral regurgitation the left atrial v-wave is greatly increased and pulmonary venous pressure rises to produce pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.
